Army Hospital Closes.—The American Red Cross Hospital at Neuilly, organized in the first week of September, 1914, by prominent Americans, including William K. Vanderbilt and Robert Bacon, and which has on a number of occasions been complimented for its work by the French Government, was closed on February 6.

Appreciation of Harvard Unit.—President A. Lawrence Lowell of Harvard University has made public a letter from Arthur J. Balfour, British Foreign Secretary, expressing the appreciation of the British Government for the work accomplished by the Harvard Surgical Unit while it was overseas. A portion of the letter reads: "Through two strenuous and memorable years the work of General Hospital 22, the largest hospital unit serving with the British Army, has held a record for skillful and untiring treatment of our wounded. The memory of so much service and self-sacrifice can never pass from us. It will be cherished in perpetuity by the relatives and friends of those whom the Harvard unit has tended with such admirable devotion."

Captain Russell W. Johnson, M. C., U. S. Army, of Jersey City, has been cited for the Legion of Honor and the Croix de Guerre by the French Government for distinguished service at Hospital No. 104, Beauvais, France, in recognition of his high moral valor and great professional ability.

Dr. Barbara Hunt, first director of the American Woman's Hospital at Luzancy, near Chateau-Thierry, has returned to this country.

Red Cross Sends Relief to Balkans.—Using Rome as a base, the American Red Cross is sending relief commissions to all of the Balkan States. A great quantity of supplies accumulated against possible needs in France and Italy will be drawn upon for Balkan relief. The work in north Serbia will be controlled by Lieut.-Col. Thomas W. Farnam, whose headquarters will be in Belgrade. Major J. P. Carey will have charge of the work in south Serbia, with headquarters at Salonica. Lieut.-Col. Edward S. Capps of Princeton will be the head of the Greek Commission. The program for Greece calls for the movement of 150 tons of supplies every week. The unit for Montenegro will be under the command of Major Edwin Grant Dexter. Lieut.-Col. Gideon H. Wells of Chicago, with a staff of sixty-five, and a supply equipment of 3,000 tons, will take care of the work in Roumania. Major G. C. Bellis, with a staff of twenty-five, will work in Albania.

Investigation Leads to Army Hospital Reforms.—After a careful investigation of conditions at General Hospital No. 1, Williamsburg, New York, by Col. J. R. Clayton of the Surgeon General's office, on complaint of the Women's Council of National Defense, a number of changes have been ordered which will ameliorate the conditions complained of, and the administration officers have been directed to endeavor by every means in their power to see that the patients have no cause for complaint.

Deaths in the Service.—Lieut. URBAN S. BIRD, M. C., U. S. Army, of Tampa, Fla., a graduate of Tulane University, New Orleans, in 1895, honorably discharged from the army on December 5, died about January 11, aged 52 years. He was a member of the American Laryngological, Rhinological, and Otological Society, for several terms city physician of Tampa, and surgeon of U. S. Volunteers, serving in Cuba during the war with Spain.

Lieut. OTTO LOUIS WINTER, M. C., U. S. Army, of St. Paul, a graduate of the University of Minnesota, Minneapolis, in 1915, chief of the orthopedic service in the reconstruction hospital, Fort Snelling, Minn., died from pneumonia, following influenza, at the home of his father, in River Falls, Wis., on January 2, aged 30 years.

Lieut. SAMUEL SOLOVEI, M. C., U. S. Army, of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1917, aged 25 years, died from pneumonia at a base hospital in Brest, on October 15.

Lieut. LEWIS WESLEY KITCHENS, M. C., U. S. Army, Senatobia, Miss., University of Tennessee, Nashville, in 1914, aged 31 years, on duty with the American Expeditionary Forces in France, died in Calais, France, on October 30, from pneumonia, following influenza.

Lieut. WILLIAM FRANCIS RAFFERTY, M. C., U. S. Army, of Rensselaer, N. Y., a graduate of the Albany Medical College, in 1911, for two terms coroner of Rensellaer County, died suddenly from heart disease while making a professional call on January 15, aged 31 years.

CARDIAC AND MENINGEAL COMPLICATIONS OF MEASLES.

IT is not perhaps a generally recognized fact that measles attacks the cardiac serosa, but such is the case, although in a much smaller percentage than other eruptive fevers, such as scarlet fever and variola, which should in this respect be placed first upon the list. Unfortunately, most writers on the subject do not state in what proportion they have observed these complications, but in Carrieu's service at Montpellier there were four cases out of a total of four hundred cases of measles, therefore 1 per cent. Of these four cases of pericarditis one presented an endocarditis as well. There is no doubt but that these cardiac complications of measles are frequently overlooked because their evolution is silent and their commencement often overshadowed by the general symptoms of the measles, for it is at the height of the infectious process and usually in the more serious cases that the cardiac serosa becomes involved.

There may be some pain in the region of the heart, dyspnea, palpitations, and a recrudescence of the fever, but in many cases none of these functional symptoms is present and the physical signs alone exist and can be detected only by very careful auscultation. There are frictional sounds and more or less distinct murmurs, almost always accompanied by tachycardia, and frequently irregularity of the cardiac contractions. When these complications arise during convalescence, their progress is also insidious and their gravity moderate. For these reasons they are overlooked, but the persistence of the dyspnea and cough after cessation of the pulmonary accidents should draw the physician's attention to the heart. Sometimes a pericarditis or an endocarditis undergoes its evolution at the same time as a complicating bronchopneumonia or a serofibrinous pleurisy, and this has led some to maintain that the cardiac lesions are secondary to the pulmonary process. But in the cases where no pleurisy exists a metapneumonic origin of the pericarditis cannot be admitted because the pleura would have become the seat of the inflammatory process before the pericardium, and cases of unquestioned authenticity have been recorded where no pulmonary lesion existed and the cardiac lesions were primary.

As to the gravity of cardiac complications of measles, it is rather a delicate question to solve, given the variety of the lesions, but it goes without saying that a pericarditis with a large fluid collection is far more dangerous than one in which there is merely a localized fibrinous deposit which may escape notice. A dry pericarditis or one with a sercfibrinous collection has been more commonly met with, and no case of purulent or hemorrhagic pericarditis complicating measles has to our knowledge been recorded. The endocarditides are of either the ulcerating or vegetative type and are extremely rare.

Notwithstanding the rather considerable number of cases of meningeal complications of measles to be found in medical literature, the question is still rather obscure. In the first place, a classification of the cases is necessary, namely: (1) The meningitides due to the virus of the measles, and (2) the secondary meningitides due to a pericranial suppurative lesion, particularly an otitis media. The latter are so well known that they are of less interest, and it is to the first class that attention is to be particularly called. Most of these offer the vulgar symptoms of meningitis, viz., headache, delirium, convulsions, contractures, etc. But usually the symptomatology is incomplete and also lacks autopsy proof. And, what is more, when an opportunity to perform an autopsy has been offered, the lesions generally have had little which was characteristic (meningeal and cortical congestion, very intense venous stasis, etc.). But in no case has a microscopic or bacteriological examination been made, and we are unaware of any instance in which during life lumbar puncture has been resorted to. Nevertheless this complication of measles does actually exist without any question. Its clinical evolution varies extremely, but death is the usual outcome after a lapse of time common to the meningitides in general and accompanied by the usual phenomena.

PSYCHOTHERAPY IN INFLUENZA.

DURING the now senescent influenza epidemic there has perhaps not been so much tendency to be facetious regarding the prevalence of the disease as has been the case in other instances. Several years ago an operation for appendicitis was considered to be a legitimate topic for serious discussion with others who had experienced it on the one hand, and good material for comedy in the humorous weeklies on the other hand. By some ingenious mechanism of compensation devised by nature the human race is consoled by misery if shared. If a hundred people in your neighborhood have influenza and you get it too it is not regarded as so great an affliction as if there were no epidemic and you alone suffered from it.

We shall not here go into any arguments re-

garding etiology. Whether Pfeiffer's bacillus, in spite of its Koch-less condition, or the streptococcus hemolyticus or some hitherto undiscovered organism, can be held responsible is still so doubtful that we only touch upon it. The fact remains that there is some sort of infection which has ravaged the world, its victims presenting a more or less uniform clinical picture, one of the salient features of which is extreme prostration.

The type of physician who accepts uncritically every case of coryza, pharyngitis, bronchitis, and so on as a case of the "flu" can do an incalculable amount of harm. The nervous, apprehensive type of patient who shudders as he reads in the paper to-day of the hundreds who have died since yesterday—and, apropos, in times of an epidemic, newspapers should be prohibited from publishing these formidable lists—is creating within himself a condition of fear and depression which cannot but be heightened when his family physician is ready to call any coincident malady the "flu." A desire to talk about the number of cases he has of the epidemic, a desire to impress the individual patient, a desire for imitation, all these things and perhaps other components enter into this phenomenon. At any rate, whatever the cause, the fact remains that many persons are literally frightened to death by an injudicious and indiscriminate nosology.

Let us then insist to our patients that even during a pandemic such as the one now subsiding every sick person is not suffering from it; let us tell them that while there may be a number of instances of the epidemic in our practice, there are many more patients who have not it at all; let us, in short, dispense reassurance instead of pathophobia.

THE PREVENTION OF DENTAL DISEASE.

Dental diseases for some time have been a fruitful subject for discussion. To an infected condition of the mouth and gums has been attributed a variety of diseases, more or less serious, and undoubtedly it is in this respect a factor of very considerable importance.

The causes of dental caries, according to Mr. J. G. Turner (*Journal of State Medicine*, September, 1918), have been shown by experiment to be two: (1) The presence of carbohydrates, starches and sugars; (2) The presence of germs. Carnivorous and grass-eating animals are free from caries. The Esquimaux used to be practically carnivorous, and it was found on examination of skulls from an old Esquimaux graveyard that they did not suffer from caries. But to day they have added fine flour and molasses to their dietary and are afflicted with caries.

It has been stated frequently by some authorities that masticating hard food acts as a preventive of tooth decay by giving the jaws exercise and that a great deal of the decay existing is due to the ingestion of soft pappy foods. However, Turner is inclined to throw some cold water on the theory and is of the opinion that big jaws and fine teeth are more a racial characteristic than a product of much use of the teeth. So far as diet is concerned, he points out that the eating of fruit decidedly cleans the teeth on account of its acid content.

With regard to the prevention of caries, Turner insists that the one essential is thorough cleaning, that is, every tooth which is exposed in the cavity of the mouth should be well rubbed once a day. The toothbrush must be supplemented by the use of waxed silk thread so as to scour each interstitial surface. At all schools a nurse's time would be well spent in teaching and supervising the cleaning of children's teeth, and such teaching should be begun at the earliest possible age. It is urged that if this plan were conscientiously carried out much of the dental caries which now exists so widely would be prevented and at the same time the sequelæ of prolonged dental disease would never occur. Turner lays down as the great principle of treatment that septic teeth are far more injurious than absence of teeth and that therefore the treatment of both caries and pyorrhea when well established should be carried on somewhat on the lines of forestry, removing some to isolate others. That artificial teeth are not a necessity is a statement with which many persons will find fault, although it is doubtless true that some of the mechanical dentistry which is undertaken nowadays does more harm than good. From the esthetic standpoint alone artificial teeth are more or less essential and the scientific dentist is as necessary for the proper conduct of the hygiene of the mouth as the all 'round hygienist and sanitarian is to the preservation and maintenance of the public health. The value of the dentist has been conclusively demonstrated by the war.

The Pest in Dakar in 1914-5.

With so much talk about the masking of other pestilences by influenza an account of the real pest in an African city should be of interest. Such an account has been supplied by Dr. Marcandier of the French Marine Service, the original report being abstracted in the *Journal de médecine et de chirurgie pratiques* for December 10. The population of Dakar is from 150,000 to 180,000 souls. The indigenous inhabitants were attacked in April, 1914, and the town was not free from the disease until the following January. The disease was not rodent-borne, and not until July did these animals participate in the epidemic. Many cattle and sheep perished of the disease. At the outset the pneumonic form of plague was alone represented. Interhuman transmission was clearly the one in action. Gradually the bubonic form supplanted it, as if the rat, when it became infected, had passed the disease along to men through flea intermediation. At the outset the new cases were disseminated and later limited to certain streets or quarters of the town. The conditions were in all respects analogous to those seen in Morocco. African plague therefore differs notably from Asiatic plague, regarded pri-

marily as a disease of rodents. The infection was probably brought from Senegal, whence it arrived from Portuguese Guinea. Upon the first appearance of the disease a vigorous campaign was instituted against it. Quarantine, sanitary cordon, isolation of suspects, incineration, segregation of the indigenous, deratisation, and antiplague vaccination were all made use of, and many thousands received immunizing injections. Three injections were given as a rule. The protection is known to be very short, but serves admirably as an antiepidemic, although when so many other measures are used its exact value is unknown. The mortality among those attacked was 54 per cent. The total number of deaths in the city were less than 1,500, and in the entire Colony less than 5,000. Deaths among Europeans numbered about half a score. The actual death rate in the city was about 1 in 100 inhabitants, the incidence therefore being about 1 in 50.

Pemphigoid Angina in Influenza

Antin, a specialist, of San Sebastian, Spain, has seen 3 cases which Professor Moure thinks worth reporting in the *Revue de Laryngologie*. The cases agreed closely among themselves and were quite exceptional in the observer's experience. The patients were males, aged 10, 20, and 28 years of age. On the second, third, and fourth days of the disease bullæ appeared upon the velum palati and anterior pillars. There had been no coryza, laryngitis, or bronchitis. This outbreak was preceded by intense pain in the throat. After puncture of the blebs the pains mostly subsided. The outbreak was accompanied by an exacerbation of fever. The first diagnosis in the young boy's case was diphtheria, which was later seen to be quite erroneous. Professor Moure, in commenting on the cases, seems to think them unusual for the present epidemic, but as having some agreement with cases seen by him in 1889-90. In this he must be quite wrong for districts other than his own; in fact, in countries where the disease has been unusually severe, as Switzerland, much emphasis has been laid on the angina, and it has been illustrated in journals for the assistance of practitioners. In England a pseudomembranous angina has been described.

News of the Week.

Reeducation of the Blinded.—"Victory Over Blindness" was the title of an address by Sir Arthur Pearson, the blind founder and director of St. Dunstan's Hostel for Blinded Soldiers, of London, England, before a mass meeting at the Century Theater in New York City on the evening of February 4. Sir Arthur described his work in restoring blinded British soldiers to self-support. The blinded men at St. Dunstan's first "learn to be blind," according to Sir Arthur. In this process they are taught to go about independently, to use the typewriter, to write Braille, to dance, to row, and to play games of one kind or another. The next step is to teach the men some vocation by means of which they can support themselves comfortably. As many as possible are sent back to their former employment. Others learn to be expert masseurs, stenographers, carpenters, and so forth.

St. Dunstan's has an extensive after-care department which looks after the interests of the men after they have returned to their homes, sees to it that their training is effective, and that they are placed in employment or provided with home work.

Lieut.-Col. James Bordley, in charge of work for blinded American soldiers and sailors and director of the Red Cross Institute for the Blind, told of the work being done at Evergreen, Baltimore, for men of the American Expeditionary Force who lost their sight in action.

The meeting was presided over by Douglas C. McMurtrie, director of the Red Cross Institute for Crippled and Disabled Men, under the auspices of which organization the meeting was held.

New York Gains by Abolition of Coroners.—The Chief Medical Examiner of New York, has just submitted his report for the first year of his office which followed the abolition of the coroners' system. This report shows that, whereas the budget for the last year of the coroners (1917) was $158,000, that for the Medical Examiner for the first year was $92,000. This latter sum covers laboratory work of the greatest value that was not done under the former system. The report shows that there were during the year 1918 273 homicides, against 283 for 1917. There was an increase of more than 50 deaths due to accidental poisoning which is attributed to the more scientific ways of determining the cause of death. The report further shows that 311 persons committed suicide by using illuminating gas, 119 by jumping from windows, 92 by shooting and 88 by hanging. There were in all 526 accidental deaths due to illuminating gas, an increase of 25 over the previous year. Forty accidental deaths were due to morphine, heroin, opium, and cocaine. The Medical Examiner's office has under advisement recommendations for having commercial poisons, such as those for the extermination of rats and insects, put up in packages that show their deadly nature, inasmuch as many persons died during the year because they mistakenly took what they thought was medicine from packages containing pure poison.

Chemists to Study Value of Medicine.—Dr. Charles A. Herty in an address before the New York Academy of Sciences, on February 3 outlined the plans of the American Chemical Society. A ten million dollar foundation for drug research is contemplated which would have for its object the acquisition of knowledge of the effect of drugs on the human body and the fundamental reasons therefore, and independence of the rest of the world, especially Germany, in synthetic medicaments. Dr. Herty states that in the fiscal year preceding the war we imported 185 synthetic medicinals at a valuation of $1,033,000, 95 per cent. of this coming from Germany. A nation-wide endorsement of this plan has been received from chemists, pharmacologists, and manufacturers.

Prenatal Work in New York City.—At the annual meeting of the Maternity Center Associa-

tion of New York, held recently at the home of Mrs. Arthur Scott Burden, it was announced that the association has established twenty-two clinics and has under its care at the present time 7,400 expectant mothers. During the coming year the association plans to open more and larger clinics and to cooperate more closely with infant welfare organizations in an effort to determine the relation of prenatal care to infant mortality. It was stated that according to the United States census 16,000 women died in childbirth last year. There are today, according to the statistics supplied by the Federal Children's Bureau, at least 75,000 expectant mothers in New York City without medical or nursing attention. Among the speakers at the meeting was Dr. Henry Dwight Chapin, who said that 700 women died of childbirth in New York City last year. The Maternity Center Association maintains a working housekeeper service so that a competent woman is always available to go into the home and assist the mother with the house work and care of other children until she regains her strength.

Measure to Legitimatize War Babies.—Judges of the Children's Court and other agencies interested in child welfare work are supporting a bill recently introduced into the New York Legislature by Mrs. Mary M. Lilly, representative from the 7th Assembly District of Manhattan, providing for establishing the legitimacy of children born out of wedlock. The bill was promoted because of the increase of illegitimacy since the outbreak of the war. The bill provides that the identity of the father must be established by a court of law and is so framed that designing women cannot resort to the law for purposes of blackmail. A number of similar measures have in times passed been introduced into the Legislature, but none has been accorded serious consideration.

Grip Masks in Australia.—Because of the widespread prevalence of influenza the Government of Victoria has ordered that every one appearing on the streets or in public gatherings after February 10 must wear a mask. In order that this regulation may be carried out seven hundred thousand masks had to be manufactured before that time. Persons appearing without masks will be liable to arrest.

Red Cross Will Form Hygiene Classes.—Plans have been perfected by the Atlantic Division of the American Red Cross to develop public interest in the formation and maintenance of classes in home hygiene, care of the sick, and dietetics. Stress is to be placed upon the education program with the object of helping women to meet emergency demands in the home in case of sudden epidemic. Efforts will made to inaugurate the courses in industrial centers and in the high schools, and local boards of education will be urged to institute the work in the general curriculum. Enrollment for these courses which are to last six weeks may be made at any Red Cross headquarters or at the teaching center at 453 Madison Avenue, New York City.

Juvenile Delinquency in War.—Early in the war there was an alarming increase in juvenile delinquency reported from the European nations, and at the time the United States entered the war such an increase was prognosticated for this country. The records of the Children's Court of New York City show that so far as New York City is concerned these gloomy prophecies have not been fulfilled. The statistics compiled by the court clerks show that during the year 13,994 children were arraigned before the court, against 14,519 in 1917, a decrease of 525. Of these 6,978 were involved in special procedings, or in action in which improper guardianship was alleged, a decrease of 300 from 1917, and 7,016 were charged with juvenile delinquency, a decrease of 216. It is believed that interesting children in various phases of war work and making them feel a certain responsibility have been large factors in bringing about the decrease in juvenile crime in this city.

Plan World Conference on Child Welfare.—Miss Julia C. Lathrop, chief of the Child Welfare Division of the United States Department of Labor, has been in conference in Paris with a number of persons from Belgium and France relative to an International Child Welfare Conference to be held in the United States in April. It is planned to have the delegates convene in Washington and then tour the country and hold meeting in localities where there is opportunity for studying at first hand the problems involved in the betterment of children.

Physicians for Rural Communities in New York State.—As a result of letters received from a number of rural communities in New York State that are without physicians because of death, permanent military appointment, or other cause, the State Department of Health has undertaken to put the authorities in such places in touch with physicians desiring rural locations. Through advertisements in medical journals and newspaper publicity replies have been received to date from ninety-six physicians located in twenty States, and names have been sent to twenty-four communities.

Hospital for Palm Beach.—Through the efforts of Mrs. Hermann Oelrichs plans are being prepared for the erection of a hospital at Palm Beach. The necessary funds are in hand, bids have been asked for, and it is expected that work will soon be started.

Post War Course in Dental Surgery.—As a part of the Post War Course in Dental Surgery that is being conducted in this city under the auspices of the Preparedness League of American Dentists, a meeting was held in the New York Academy of Medicine, on February 8, at which Major Tait MacKenzie of Philadelphia, who served with the British Royal Army Medical Corps, gave an illustrated lecture on "Facial Prothesis and Appliances for Restoring Lost Function." Major Fred H. Albee, in charge of the United States General Hospital at Colonia, N. J., gave a motion picture demonstration of "Bone Grafting as Applied to Oral Surgery." The object of these lectures was to demonstrate to physicians and surgeons what could be done in case of injury of the face or jaw to restore function and secure a good cosmetic effect, even though they might not attempt to do this work themselves.

Pantagruel fell asleep, holding in his hand a copy of the Greek author Heliodorus.[9] He undoubtedly had chosen this author intending during the large leisure of an indolent day to be edified. In the same way I knew a most estimable woman, who, on every drowsy Sunday afternoon, would seat herself in a rocking chair with her Bible. Presently the Bible would be in her lap and she would be asleep.

In Rabelais' day the church was a career much more frequently entered than it is to-day. It was an enormous institution with immense revenues, and an infinity of places paying a small salary. Just such places as are loved by those who desire a secure living and an easy life, and yet whose wants are few. A very mediocre education in one of the universities was enough to obtain such a place, and this partly explains the great crowds of poor students who attended these seats of learning. Having secured the church living, the tendency was for the occupant to fall into routine, and to enable one to do this without embarrassment there was published a very popular book of sermons called the "Dormi Secure" or Sleep in Peace. The title meant that the preacher might sleep soundly and not arouse himself in the morning in order to compose his sermon, as sermons suitable for every conceivable occasion were all duly set forth in this convenient book.[10]

Rabelais was a monk, and although the word means "alone," it came, as Chesterton says, to mean a community, and a very close-knit intimate community. People when intimately thrown together for long stretches of time, as in camping parties or on yachts, become disagreeably aware of peculiarities in their neighbors, and Rabelais touchingly refers to snoring.

Carpalim, the swift one, went lightly among the Dipsodes and Giants, whom Pantagruel was besieging, and they did not remark him, so profoundly did they snore and sleep. So successful was he that he reached the place where they kept their artillery and set fire to their munitions, and ran considerable danger to his own life from the rapidity with which the powder blazed up.[11]

In another situation Rabelais mentions a community where the people gained their living by sleeping, and those who could snore the loudest made the most money.[12]

Alcohol As a Soporific.—In his famous enumeration of the five means of restraining carnal concupiscence, Doctor Rondibilis begins with wine. He had hardly got the words will out of his mouth when Friar John broke in with "I can well believe it, for when I am drunk I only want to sleep."[13]

It has been supposed that sleep is produced by a sort of soporific agent generated by our cellular activities while we are awake. The state of being asleep, however, is probably as normal as being awake, and it would be just as logical to suppose that during sleep an exciting agent was generated, which, when enough was produced, aroused the individual to conscious activity.

And what a mysterious event natural awaking is! To paraphrase Ambrose Bierce: What whispers into the ear of our spirit the mysterious awakening word which no human lips ever have spoken, no human memory ever has recalled?[14]

Howell believes that the regulation of the vasomotor system involved in the occurrence of sleep is effected mainly through variations in the cutaneous circulation.[15] This might explain the importance of sleep in the cure of many diseases of the skin involving the vascular system, as for example, eczema. We are accustomed to say that when a patient suffering from acute extensive eczema begins to sleep well his recovery is assured; even chemically induced sleep, as by bromide of potassium, is frequently a great aid in the treatment of such cases.

The most rational view of sleep seems to be that it is a periodic or rhythmical state of repose, which appertains to all cellular life, from the contractile vacuole of the ameba to the heart of man; the heart-beat, indeed, is the most striking example of this rhythmical succession of work and rest. It has been even calculated that the heart works just eight hours out of the twenty-four—that its contraction, its expansion and its period of rest correspond to eight hours of work and sixteen of rest. Many of our functions and our desires are periodic, hunger, for example; and our whole life, in the larger sense, is a period—we are born and after a period we die. The activities set up in the egg, and probably stimulated by fructification, exist for a period varying with the animal and then cease.

DISTRESSING GENERAL AFFECTIONS TRACEABLE TO EYE CONDITIONS.

By J. A. KEARNEY, M.D.,

NEW YORK.

PROFESSOR OF OPHTHALMOLOGY NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

By a process of elimination of the probable causes of distressing general affections, a decision is usually finally obtained. Among the most frequent sources are irritations existing somewhere in the body, toxemias of various origins, and undue loss of nervous energy.

In the studies of elimination, errors of refraction and extrinsic ocular muscle imbalance are very often found to be fruitful sources of undue loss of nervous energy. Roughened and dry palpebral conjunctivæ most frequently produce irritations of consequence, although disturbances of other ocular tissues are held accountable for some conditions. It is surprising to note in some cases the marked reduction or entire loss of symptoms that takes place following the clearing up of a dry and roughened conjunctiva.

Headaches of various characters, malaise, vertigo, chorea, insomnia, melancholia, neurasthenia, flatu-

and later consulting physician to St. John's Hospital, Lowell, Mass., director of the school of hygiene in the Boston public schools from 1907 to 1915, instructor in the school for teachers at Harvard and the Massachusetts Institute of Technology, physician in chief of St. Elizabeth's Hospital, originator of "health days," and author of the History of Harvard Medical School. He held the rank of lieutenant-colonel in the Medical Corps of the Massachusetts V. M.

Dr. W. STANTON GLEASON of Newburgh, N. Y., died of Bright's disease at his home on February 3, aged 58 years. He was a graduate of New York University Medical College in 1886, a member of the American Medical Association, and the New York Academy of Medicine. He was senior attending physician to St. Luke's Hospital and consulting physician to the Highland Hospital and to St. Francis Hospital, Poughkeepsie. Dr. Gleason was a former president of the Medical Society of the State of New York.

Dr. PHILLIPE SHARPLESS HALL died at Philadelphia on January 16, at the age of 51 years. He was graduated from Hahnemann Medical College of Pennsylvania in the class of 1891. He was at one time professor of pathology in his alma mater, and he was a member of the American Institute of Homeopathy.

Dr. RALPH E. SHROM died at Philadelphia on January 26 as a result of pneumonia complicating influenza, at the age of 37 years. He was a graduate of Jefferson Medical College in the class of 1904, and he was a lieutenant in the United States Naval Reserve. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. ALBERT A. G. STARCK died of heart disease at Philadelphia on January 30, at the age of 67 years. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. JAMES H. WILSON died at Dover, Del., on February 1, at the age of 77 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1867. He was a member of the Kent County Medical Society, of the Medical Society of the State of Delaware, and of the American Medical Association. He had been since 1874 surgeon to the Delaware Railroad, at one time a member of the Dover Board of Education, for many years a member of the board of trustees of the State Hospital at Farnhurst, and he was secretary of the Medical Society of Delaware Examining Board.

Dr. WM. CHARLES GRIGGS died of heart disease at Philadelphia on February 2, at the age of 52 years. He was graduated from the University of New York Medical College in the class of 1890, and, after the usual hospital interneship, began practice in Philadelphia. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. CHARLES HENRY RILEY, a graduate of the University School of Medicine, Baltimore, in 1880, died of a complication of diseases following influenza, at his home in Baltimore, on January 23, aged 63 years.

Correspondence.

NO FRATERNIZING.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Signs are not wanting that the propaganda of intrigue and crime of the German is continuing in this country. Conquered by the triumphant Allies and forced to abject military surrender, he is unrepentant, unchastened, arrogant. He counts upon being rehabilitated and is even now making ready to come to America to live among us and enter into competition with the relatives and fellow countrymen of those whom he murderously slew on the high seas. American soldiers released from German prison camps have told of the doctors who treated their wounds, making inquiries about our country and remarking casually that they expected to come here to practise as soon as peace was declared. They seem not yet to sense the utter contempt in which the world holds them.

The baby killing, fruit tree murdering, woman violating vandals have been stopped in their criminal career by the armies of General Foch. That this great soldier knows the duty of the hour is shown by the just and stringent terms of the armistice of November 11, and by the increasing severity of the subsequent renewals of this armistice. We need have no fear regarding the military conditions.

We may well take thought, however, of the insidious propaganda going on in this country to prepare a welcome for these bombers of hospitals and slayers of the innocent, their hands still stained with the blood of babes and virgins. "The less said the better," says one; "Let bygones be bygones," says another; "The *Lusitania* is old stuff now," says a third.

It is our duty to counteract this propaganda, so far as it concerns the medical profession at least. This generation must be through with the Boche and with all his works. The next generation may decide what it will do with him. The duty of the hour demands that all Americans keep the unregenerate Hun for the present on the other side of the water. Extended service in France has impressed upon me most deeply the extreme importance of debarring the Germans from all professional relations with us.

CHARLES A. POWERS, M.D.

THE HEALTH INSURANCE BILL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I beg to call your attention and that of your readers to the enclosed letter to the President of The Medical Society of the State of New York. It will require the early and united action of every physician in the State in the manner indicated in this letter to defeat for the fourth time the scheme for "Compulsory Health Insurance" now disguised as "Health Insurance."

Never before has this promotion worn so dangerous an aspect as at the present time. The trade mark "Yours for Health," long monopolized by the late, if ever existent, "Lydia Pinkham," has been appropriated bodily for political purposes in the highest political quarters.

JOHN P. DAVIN, M.D.

117 WEST 76TH STREET, NEW YORK.

T. H. Halsted, M.D.,
President Medical Society State of New York,
Syracuse, N. Y.
Dear Doctor:

In duty to the standards of our profession and to the welfare of the public whom we serve, I would like to call your attention, and that of the Council of the State Society to a measure now before the Legislature, and recommended for passage by the Governor in his message to the legislature.

This measure is a bill for what is called "Health Insurance." It is the same one essentially, which under the name of Compulsory Health Insurance has been defeated three times already by the efforts among others of the entire Medical Profession of this State. It is now advocated by the State Industrial Commission, and by a socalled "Association of Manufacturers." There is no evidence that the public and the medical profession upon whom would fall the loss and burden accruing from the passage of this measure have been consulted in any way in regard to its provisions.

At an initial outlay of $1,500,000 it would place upon the State Board of Health the duty of assuming charge of the health of the working population of the State, as well as those who would apply to it for special advice or treatment. It is a political attempt to put into practice the theory of the "Socialization of Medicine," at a time when the political socialization of every other form of enterprise is falling into disrepute.

Hitherto the State Society has waited until the eve of the passage of medical laws, before entering its protest formally before the legislature. On all such occasions we have received but a perfunctory hearing before a body more or less biased against an attitude of opposition to its findings.

I would suggest, now, that this matter be placed before every county medical society in the State for their immediate consideration, the results of which to be forwarded by the secretaries of these societies to the members of the legislature representing the various counties in the State. In this way the profession would command a hearing and compel a respect for their representations that hitherto they have not been able to command when this duty was delegated to a committee appearing before the legislature generally at the eleventh hour of its session.

Respectfully submitted,
JOHN P. DAVIN, M.D.,
Member Medical Society County of New York.
Secretary, Association for Medical Defence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 17, 1919.

Position of the General Practitioner.—The position of the general medical practitioner in England after the war is a matter that must remain to a certain extent the subject of speculation. At the same time the relegation of all consideration of the subject to some future period when there is definite material to work upon is a lazy and mischievous policy. Though we may not know exactly what is going to occur in many phases of medical life we are not without perfectly definite grounds for knowing that some things must happen and that others will not. The developments of medicine are an expression of national activities and will follow, supplement, or (still better) initiate improvements in those activities, and the leaders of medical thought in England, seeing that the reins of government are surely going to be assumed by the people, are trying to bring the medicine of the future into touch with popular needs. The task is not an easy one for while the science of medicine is all that is progressive, medical politics are apt to be terribly conservative.

Before the war to a great extent the life of the English general practitioner was not ordered on professional lines along which scientific progress and development were likely to be made. Let us take 45,000 as the total number of all the medical men in the United Kingdom actually alive. From this bulk we have to abstract, as well as those who had retired from practice through age or disinclination, three main bodies, namely: —the consulting class, men who held the hospital appointments, with their adjuncts of scientific, special and laboratory facilities; the official class, men who as officers in the service of the local government board, the Home Office and other departments, were in touch with the public in the discharge of their official duties but looked to Government authority for pay, pension and promotion; and the officers in the navy, army, Indian Medical Service and Colonial Service, who similarly were not directly dependent upon the public for the reward of their labors, however intimately those labors were concerned with that public. What remained over was the general practitioner class, at the one end of which we had the most highly equipped medical men whom, in a general sense, our good though anomalous system of education turned out, and at the other end the rank and file, concerning whose merits there can be absolutely no doubt. Without any individual distinctions this last and most numerous body form one of the most highly standardized bodies of educated men in the country. Everyone of them has made good in a series of prolonged tests laid down upon a general pattern by the Privy Council through the General Medical Council, and no one who knows anything about the work of the general practitioner of England can fail to see that some of the most competent clinical work discharged in the country is discharged by them; and as much by general practitioners engaged in panel practice as by others. Immediately before the war the panel practitioners under the National Insurance Act, numbering at least 14,000, had just got to work and while the good and the bad of the new system was becoming apparent, as well as the direction in which reform would be called for, the war broke out, and one-third at least of these men became temporary medical officers with the fighting forces. Such was the position before the war.

During the progress of the war, for reasons so obvious that they need not be dwelt upon in any detail, it became apparent to the country that national health was the greatest national asset and that the medical profession, especially the general practitioners who had the actual care of the sick population, were the class upon whom the actual responsibility devolved of maintaining national health. This view was accepted by statesmen of all caliber and politicians of all brands, and various schemes were mooted, having the same objective and most of them taking for granted that the promptest way of dealing with the situation would be to set up a Ministry of Health, a department in which would be centered

the care of the health activities of the nation. This is boldly and roughly the existing situation and the question is what concrete plans will be made immediately to meet it, and in those plans what part the general practitioner will be asked to play. All are aware now that the care of the health of the country is a matter of cooperation, first between the public and the medical profession, and secondly between all the branches of that profession. Official medicine must work hand-in-hand with the general practitioner. Medical men of special attainments, possessing particular scientific facilities, must fuse their energies with those of their brethren who are daily in contact with sick masses and whose treatment of these masses in bulk requires to be supplemented at all times and in every direction with the highest aid which can be given by modern knowledge. It is not that the general practitioners of the country must be given a chance to work along these lines; it is rather that *unless these are the lines upon which the developments of the future are made medicine will lose the service of the right sort of men.* The idea that there are consultants and officials and some others must entirely disappear out of the theories of education and out of bureaucratic legislation, and the promptitude with which they will so disappear would be remarkable if a real Ministry of Health were instituted in which the conditions of service for the general practitioner were fairly arranged. There must be local consulting centers, facilities for the transport of hospital patients from rural districts, extensive support of bacteriological laboratories as as an adjunct to provincial practice, and real intercommunication between the official and the general practitioners. Unless these things are provided for the Ministry of Health will not minister to health.

A Special Clinical Meeting of the British Medical Association.—The customary annual meeting of the British Medical Association will not take place in 1919, but will be replaced by a special clinical meeting to be held early in April. The annual meetings, which have been suspended for the last four years owing to the war, will be resumed in 1920, the seat of the meeting being Cambridge.

The Vaccines and Serums Supplied to the Royal Navy.—Previous to 1916 the greater part of the vaccines required in the Royal Navy were received from the inoculation department of St. Mary's Hospital, London, under the superintendence of Sir Almroth Wright. But since that date the navy has made itself responsible for its own vaccine-therapy, and vast quantities of vaccines and serums have been prepared in the laboratories of the Royal Naval College at Greenwich by the naval staff. The part played by vaccines and serum in the prevention of disease and the treatment in the Royal Navy is sufficiently indicated by the following summary of quantities prepared, which has been published by Captain P. W. Bassett-Smith, the professor of pathology and lecturer on tropical medicine at Greenwich College: Typhoid vaccine, 5400 c.c. Paratyphoid vaccine, 21,500 c.c. Triple typhoid vaccine (Naval formula), 247,700 c.c. The triple vaccine is a mixture of B. typhosus, paratyphosus "A," and paratyphosus "B" heated to 55 deg. C. for half an hour, 0.5 per cent. phenol is then added. Cholera vaccine, 8600 c.c. (Prepared from several strains of Balkan origin.) Antisepsis vaccine, 48,400 c.c. (A mixed polyvalent vaccine containing streptococci and staphylococci.) Influenza vaccine, 144,000 c.c. (A mixed polyvalent vaccine containing *B. influenzæ*, streptococci, and pneumococci.) Melitensis vaccine, 1380 c.c. Staphylococcic vaccine, 910 c.c. Tetanus antitoxin, 14,800 doses. Diphtheria antitoxin, 2400 doses. Antidysenteric serum, 2800 doses. Antistreptoccic serum, 1250 doses. Antimeningococcic serum, 5000 doses (and others in smaller quantities). Vaccine and serum treatments have their finest opportunities in the Royal Navy. The men are subjected to risk of every conceivable sort from tropical diseases, while the conditions in which they live make concealment of the conditions impossible, and dates of infection certain. Moreover the blue-jacket is an extraordinarily good patient, brave, disciplined, and eminently healthy and wholesome.

8. Some Pathological Conditions of the Mouth and Their Treatment.—Chalmers J. Lyons points out the responsibility that rests with the educated dentist of the present day whose duty it is to make a thorough examination not only of the tooth surfaces, but of the mucous membrane, tongue, tonsils, pharynx, and salivary glands. Although the *x*-ray is indispensable in dental practice, other factors must be considered in arriving at a diagnosis; the pathological must be differentiated from the physiological and the radiograph employed as a further means of reaching a definite conclusion. One of the most perplexing problems met with is that of obscure pain localized in the jaws. Healthy teeth are frequently sacrificed in an endeavor to eliminate a possible source of socalled neuralgia, whereas the real source of the pain may be a paratonsillar abscess or a tooth in the other jaw. Goldscheider has suggested that in the Gasserian ganglion there are certain nerve cells which have either split fibers or two separate nerve fibers, one running in one division of the fifth nerve and the other in one of the other divisions of the same nerve. If the source of infection is in either the second or third division of the fifth nerve, a diagnosis can usually be made by blocking off a section of the branch and observing the results. In regard to tic douloureux, it is contended by many able brain surgeons that its etiology is of central origin. Neither removal of the teeth, nor injections of alcohol, nor even neurectomy offer permanent relief, and in the author's opinion operation on the ganglion itself is the only means of obtaining this. Another type of referred pain is that arising from an old syphilitic lesion. This improves under antisyphilitic treatment. The primary lesion is frequently found on the lip or on the tonsils; seldom on the cheek or tongue. It can be differentiated from certain forms of stomatitis in that the chancre is painless and usually causes enlargement of the lymph nodes. Secondary syphilitic manifestations of the mouth are usually of an erythematous or ulcerative type, commonly seen on the oral pharynx as an in-

flammatory area, attended by little or no pain. Mucous patches may be observed on the edge and tip of the tongue, on the dorsum of the tongue, uvula, and fauces, or on the inner surface of the lips. They are irregular patches of greyish white color, covered by a sticky secretion and may be differentiated from other lesions in that they are unaccompanied by pain. Gummatous ulcers in the mouth—tertiary syphilis manifestations—may be mistaken for carcinoma. On the tongue they usually appear over the whole upper surface, whereas carcinoma would be confined to the edge or one side of the tongue. Carcinoma, however, frequently supervenes on an old syphilitic lesion. In all cases suspected of syphilis, nothing should be done until a Wassermann test has been made. Leucoplakia is a precancerous condition which is invariably caused by excessive use of tobacco. The similarity between leucoplakia and secondary syphilis is often confusing. Syphilitic plaques usually appear on the border and back of the tongue and at the same time other patches may be observed on the gingiva, palate, or tonsils. They are soft, whereas those of leucoplakia are hard. Since the dentist has opportunity of observing precancerous conditions long before the physician sees the patient—when it is frequently too late to eradicate the disease—it is the duty of the dentist to direct the patient's attention to such conditions and, if possible, to have a microscopical examination made. Dentigerous cysts are frequently seen in the mouths of men and women under thirty, and may be mistaken for a tumor or an alveolar abscess. They may be differentiated from an osteoma since fluctuation and crepitation can usually be elicited. They differ from alveolar abscess in that they are very slow in formation and not accompanied by pain. These cysts should be widely opened and the unerupted tooth or tooth follicles and the cystic lining removed. The author has obtained good results from packing the cavity with iodoform gauze and irrigating with five per cent. salt solution every twenty-four hours. Absorption of bone is the most serious sequela. Epulis occurs frequently in childhood and in young adults, and is more common in women. There are two varieties—the fibrous and the giant cell, the latter being the more frequent. Growth is slow at first but becomes rapid as the tumor progresses, causing the teeth to spread apart with consequent loosening. The tumors, which remain attached to a small stalk, are benign at first but later become malignant. They should be removed as soon as identified, and examined microscopically. The portion of the periosteum or alveolar process to which they are attached should also be removed, and actual cautery employed to sere over the wound. Another important and not infrequent pathological condition of the mouth is Vincent's angina, which is characterized by a deep tissue necrosis, covered by a whitish grey membrane. This membrane is easily removed and when rubbed off leaves a granular, raw, bleeding base, which leads to craterlike ulcers with irregular edges. The condition is infectious but prognosis is usually favorable and if seen early, these cases can be easily controlled. In disease of the antrum of Highmore, the author believes that closer cooperation between the dentist and the rhinologist is needed. Three principles must be kept in mind in the treatment of empyema of the antrum: the source of irritation must be removed, drainage must be established, and ventilation must be maintained. A correct diagnosis is of the utmost importance, as it is essential that the source of irritation be removed or the opening will not close. The author then turns to morbid conditions involving the pericemental membrane. The difficulty here is to decide whether to extract the tooth or to perform root resection. This again is largely a question of diagnosis. The health, age, and recuperative force of the patient must be considered, as well as the condition of the blood supply to the apical area; that is, it must be decided in each individual case whether or not conditions are favorable to normal repair of bone. The proper evaluation of x-ray findings is of great importance. If the case is one of alveolar abscess of long standing, or a case of imperfectly filled root canal with granuloma showing in the apical area, surgical procedure is indicated. Before root resection is done, a crown or bridge attachment should be removed, the canals and dental tubules thoroughly sterilized and the canals filled; otherwise reinfection will occur. Sterilizing and completely filling canals in multirooted teeth for the eradication of an infection the author considers a doubtful procedure, believing that the patient's welfare would be better safeguarded by extraction followed by curettage of bone. This operation should not be resorted to when the bone and pericemental membrane are diseased beyond the apical third of the root.

5. Slow Intravenous Injection of Antiserum to Prevent Acute Anaphylactic Shock.—Julian H. Lewis reviews the various methods tried from time to time in an effort to prevent anaphylactic shock. The use of hypertonic salt solution was found to diminish anaphylactic shock in animals but there are no reports of the use of this procedure in man. The methods usually employed are those worked out by Besredka, namely, the administration of minute single or repeated doses of antigen three or four hours before the full injection is given, or the rectal injection of from 5 to 10 c.c. of serum, when gradual absorption of antigen occurs. Another method, suggested by Friedberger & Mita, is that of slow administration rather than division of dose. It having been shown that the danger of serum sickness was influenced by the size of the dose, the logical procedure was the production of antiserums with a higher concentration of antibodies. But though it was possible—particularly in diphtheria—to give large doses of antibodies in a small volume and thus lower the severity of anaphylaxis, serum sickness was not prevented. In the case of pneumonia, the concentration of antibodies has not been successfully accomplished and furthermore the promulgators of the use of antipneumonic serum advise the direct intravenous injection of doses as large as from 50 to 100 c.c. These two factors no doubt are responsible for the serious anaphylaxis reactions reported from army camps. The author believes that the slow protracted injections of diluted serum, as advocated by Friedberger and Mita, is the method best adapted to the conditions, particularly if the Woodyatt pump is employed. The results of animal experimentation have led him to the following conclusions: That acute anaphylactic shock can be prevented in sensitized experimental animals by giving otherwise fatal doses of diluted antigen intravenously at very slow rates. That so far as these results can be applied to man, it is to be recommended that when immune serum must be given intravenously, it should be given slowly and in a diluted form, the Woodyatt pump serving as an excellent means of doing so. The exact quantitative relations must be worked out experimentally with patients. At present it can only be said that the injections should be made as slowly and the dilutions should be as high as is convenient or necessary under a given set of conditions.

8. Empyema Following Influenzal Pneumonia.—Major Max Ballin gives the results of his observations on the epidemic which occurred at Camp Grant, Ill., in September and October last. He points out that in the treatment of empyema it is necessary to differentiate between three types: (1) The empyema following hemolytic streptococcus infection, which occurs early as an exudate in the first week of the pneumonic process, is thin, very copious, and capable of being absorbed, and should be handled, if necessary to relieve pressure, with aspiration, operating by costectomy only after the pneumonia has subsided. (2) The empyema following lobar pneumonia. This sets in four weeks

after pneumonia, is of good prognosis, and can safely be handled with costectomy. (3) The empyema following influenzal pneumonia. This also develops four weeks from the onset of the process. On account of serious and frequent metastatic suppuration, its prognosis is more severe than that of form 2. It is best handled by thorough drainage, by costectomy under local anesthesia. Major Ballin emphasizes the importance of local anesthesia in operations for empyema, in view of the frequency of sudden death from suffocation under general anesthesia. He describes the technique of the operation and states that of seventy-nine patients operated upon eleven died, all of whom, however, had severe complications. The first thirty patients were treated with neutral solution of chlorinated soda, every attention being paid to the details of administration, and of this group eight died. The remaining forty-nine patients were given dry treatment, with three deaths.

4. Meningococcus Bronchopneumonia in Influenza.—Captain William Fletcher submits the results of a study of 36 fatal cases of bronchopneumonia which occurred in American soldiers, in 11 of which Pfeiffer's bacillus was found in association with the meningococcus. The other cases were due to combined infection with this bacillus and pneumococci or streptococci. Beyond possibly a greater tendency to hemoptysis, there were no clinical signs to distinguish the cases of meningococcus bronchopneumonia. None showed any signs of meningitis before or after death. Summarizing these cases, the author states that: (1) In the postmortem examination of 36 men who had died from bronchopneumonia following influenza, Gram negative cocci were the predominant organisms found in the lungs of 11 cases. (2) All the men, with one exception, had been taken ill on board the same transport. (3) In six cases these Gram-negative cocci were Type II meningococci and in one case they belonged to Type I. In four instances the cocci were not tested by agglutination. (4) In each of the 11 cases Pfeiffer's bacillus was found in symbiosis with the Gram-negative cocci. (5) The meningococcus, like other "respiratory" organisms, may, when it occurs in conjunction with Pfeiffer's bacillus, produce a fatal bronchopneumonia.

4. Note on a Case of Acute Febrile Polyneuritis.—R. W. Dale Hewson and R. M. Stewart report a case of acute febrile polyneuritis which, as far as the authors are aware, is the first that occurred in the British Salonica force. The symptoms exhibited conformed closely to those described by Holmes in the cases that occurred in France. The sudden onset of illness in a healthy man with feeling of malaise and slight fever, but no shivering, vomiting, sweating, or other symptoms characteristic of malaria, the rapidly developing flaccid motor paralysis, the implication of certain cranial nerves, the early loss of sphincter control, and the relatively insignificant sensory changes. The lower limbs showed a marked degree of paralysis, but no individual movement was impossible, nor were the distal segments of the limbs more paretic than the proximal. Muscular atrophy occurred to a very slight degree. The muscles of the upper limbs were much less severely affected. No affection of the intercostal or abdominal muscles was noted. Complete paralysis of all muscles innervated by the seventh cranial nerves was observed on the third day of the patient's illness, and formed a striking feature of the clinical picture. Articulation was slurred and indistinct. Neither the tongue nor the palate was involved, but the patient experienced difficulty in swallowing. There was no involvement of the muscles of mastication, and phonation was unaffected. The reactions of the pupils were normal, but paresis of the left external rectus was noted, and the patient complained of occasional double vision. Cutaneous sensory disturbance was very slight. At first slowness of perception of tactile and painful stimuli was noted, and at a later date a raised threshold for the appreciation of simultaneously applied compass points. Joint sense and vibration "sense" were apparently normal. The abdominal and plantar reflexes were absent; also the deep reflexes (except the triceps jerks). Incontinence of feces existed for two days. There was no disorder of mental functions. Definite improvement was noted twelve days after the onset of the symptoms. Examination of blood, the cerebrospinal fluid, and the urine yielded negative results. It remains to be noted that in one or two particulars the patient did not conform to the usual clinical features. While sphincter trouble was very transient, the difficulty in swallowing persisted up to the time of the patient's evacuation from Macedonia. Paralysis of the diaphragm, not hitherto recorded, was present in this case. The proprioceptive forms of sensation, which are said to be frequently involved, were unaffected. Although a typical malarial attack occurred on the twenty-first day of illness, the parasite of benign tertian fever being demonstrated in the blood, the authors are of opinion that this fact furnishes no conclusive proof that the case reported was conditioned by the malaria toxin. There was no history suggestive of malaria, nor was the parasite found until the patient had been three weeks in hospital. Moreover, a differential blood count gave normal results. The authors, however, base their opinion chiefly upon the fact that in cases of post-malarial multiple neuritis that have come under their observation, the clinical features have been very different from those described in the case reported. The recent occurrence of a variety of polioencephalitis in epidemic form in the British Isles suggests the presence of some such pathological basis, but the complete integrity of the mental functions and the clinical course of the symptoms observed in this case, renders such an etiology extremely unlikely.

Berliner klinische Wochenschrift.

December 2, 1918.

The Serum Treatment of Diphtheria.—A. Czerny sums up the present state of uncertainty regarding the real value of the serotherapeutic treatment of diphtheria since Bingel declared, with statistics to back him, that the action of simple horse's serum was equal to that of prepared horse's serum. The recent discoveries on the curative action of albumins injected in the muscles or veins would seem, in fact, to divide the efficacy of antidiphtheritic serum between serum albumin and antitoxin properly speaking. However, until more extended experimentation, there is no reason for changing the classic treatment of diphtheria with specific serum in any way.

The Forms of Septicemia Due to the Bacillus of Tuberculosis, the Typhobacillosis of Landouzy, and Miliary Tuberculosis.—M. Scholz brings forward to illustrate this still much debated subject an interesting case. The patient, a woman fifty-six years of age, ill for three weeks with a symptomatology entering into

the typhoid class, without, however, showing any roseola. The sterility of the blood led the writer to conclude that the case was one of miliary tuberculosis. At autopsy there were no granulations visible macroscopically and only the usual pathological changes of a septicemia were noted, but microscopically small foci of necrosis containing acid-resistant bacilli were discovered in the liver, spleen, and other viscera. Scholz states that this clinical observation would be placed in the class of Landouzy's typhobacillosis; however, he refuses to regard this as a form of disease and prefers to call it superacute tuberculous septicemia. He points out that the anatomic status does not differ from the classic miliary form other than by an absence of granulations and that this difference is the result of the reactivity of the patient and that therefore it should not be transferred from the general class of miliary tuberculosis. The possibility of such septicemic varities with a mild evolution, such as Landouzy describes, cannot be entertained according to the writer's view, since the absence of miliary granulations should be regarded as improper for maintaining this theory. A rather complete bibliography is appended.

Münchener medizinische Wochenschrift.

November 26, 1918.

The Functions of the Human Appendix.—K. Peter desires to oppose the tendency to look upon the appendix as a rudimentary organ of no use. A foundation of value for the assertion that this organ is useless cannot be found either in comparative anatomy or embryology. From its structure the appendix belongs to the group of lymphoepithelial organs and therefore is similar to the thymus, tonsils, etc. (a fact known for the past thirty years or more but coming from Germany it must be new). Although recognizing that removal of the organ does not unfavorably influence the general health, Peter attributes a function to the appendix which is as yet enigmatical.

The Prevention of the Phenomena of Hypersensibility in the Parenteral Exhibition of Heterospecific Albumin.—E. Friedberger, well known for his theories relating to anaphylaxis, recalls the procedure of small doses employed with the object of preventing anaphylactic reactions when giving animal sera. This procedure of sensibilization attains the maximum of its efficacy when the injections are given as progressively in amount as possible. The writer describes a simple form of syringe which permits giving a slow, graded injection. Experimental researches have shown that his manner of procedure allows one to go far beyond the ordinary fatal dose to the extent of twenty times its strength in sensibilized animals.

The Triceps Muscle Used as a Motor Force in Prostheses.—H. Böhm studies the deformity produced by transversal section in an amputation stump when the triceps contracts. This change can be utilized for transmitting, by means of a pulley, traction in the direction of the axis of the arm and this mobilizes the parts composing the prosthesis. In the same way the movement of rotation of the humerus in the axis of the arm can be utilized for accomplishing movements of pronation and supination in the artificial limb. The writer gives a figure showing the mechanism of the principles laid down.

Deutsche medizinische Wochenschrift.

November 28, 1918.

Silver-Sodium Salvarsan.—Galewsky gives a favorable report on this product, put on the market by the bacteriologist Kolle, which accords with the writers on the subject already noted in these abstracts. The product possesses an energetic action in much smaller doses than required by neosalvarsan. The writer is of the opinion that this higher efficiency is due to the combination of metallic silver with the salvarsan radicle and that it results that Kolle's product avoids the dangers of intensive arsenical treatment while assuring the same therapeutic effects. The most evident results are obtained in luetic manifestations on the mucosæ, either of the secondary or tertiary types. The product, like Ehrlich's original 606, is patented and the numerous articles describing it are evidently in the nature of advertisements.

The Serum Treatment of Influenza.—E. Reiss has injected various sera in influenza patients, such as normal human serum, serum obtained from those convalescing from the grippe, normal horse serum, antidiphtheritic serum, etc. Generally speaking, the writer noted a marked improvement following these injections at the end of thirty-six hours. The best results were obtained with the serum of convalescents and normal horse serum. The writer is of the opinion that the good results are due to a general action of the serum as a blood serum *per se*, rather than to a specific action.

Variola Without Exanthema.—Kathe insists upon the importance of these cases from the viewpoint of epidemiology, and relates some recent experiences. The cases observed by the writer offered a rise in temperature and general signs common to variola. Out of a total of five cases only one offered an eruption which was characteristic of the disease and therefore gave the clue to the real condition of affairs, the other four patients going through their variola without an exanthema or pustules. The writer attributes this mild evolution to vaccination which all soldiers had received at the beginning of the war. From the viewpoint of contagion it goes without saying that these patients are quite as dangerous, even more so, than frank cases on account of the possibility of overlooking the correct diagnosis.

Le Progrès Médical.

December 14, 1918.

Intravenous Injections of Camphorated Oil in the Asphyxiating Types of Grippe.—Loeper and Fumouze do not include pneumonic forms under this head. In the type referred to the patient is stricken in the midst of apparent health with fever which is not as high as a rule as in pneumonias. The skin is very pale, excepting where cyanosis is present and severe dyspnea is prominent of a form suggesting uremia. The physical signs do not reveal any one focus of disease in the lungs, but the râles heard everywhere suggest congestion and edema. Expectoration is scanty, but hemoptyses sometimes occur. This does not always mean that there is no secretion in the air passages, for some patients are unable to rise and are suffocated by their own secretions. The heart is weak and dilated and its action very rapid. Seven autopsies agreed in showing a mixture of infarcts, congestion, and edema with absence of pneumonic foci. As a rule albuminuria was present and acute uremia was thought of, but examination of the blood showed absence of retention of urea. The whole picture suggests an intoxication of unknown character which attacks the bulbo-vagus system. The untreated patients with these forms have invariably perished in two or three days. Next to the thoracic organs the nerve centers suffer, as delirium and mental confusion are usually present. The treatment of these cases must be heroic and consist of venesection with infusion of adrenalized serum and camphorated oil injected into the venous system. The authors have with this treatment cured twenty out of thirty-eight cases, which in a disease of 100 per cent. mortality is very satisfactory. The amount of camphor injected is 2 c.c. of a 10 per cent. solution daily throughout the course of the disease. The immediate effects are very striking, as the entire disease picture improves promptly.

December 26, 1918.

Minor Forms of Graves' Disease.—Lian discusses this much described syndrome, apparently because it is still far from being clarified. If a subject have palpitation and tachycardia has he an abortive form of Graves' disease? The question is a delicate one to decide. We have no biologic reaction to settle it and must depend on resources of some sort to differentiate between this and other forms of tachycardia. Paroxysmal attacks are at once excluded as far as the latter is concerned, for there must be a permanent acceleration of the heart

the care of the health activities of the nation. This is boldly and roughly the existing situation and the question is what concrete plans will be made immediately to meet it, and in those plans what part the general practitioner will be asked to play. All are aware now that the care of the health of the country is a matter of cooperation, first between the public and the medical profession, and secondly between all the branches of that profession. Official medicine must work hand-in-hand with the general practitioner. Medical men of special attainments, possessing particular scientific facilities, must fuse their energies with those of their brethren who are daily in contact with sick masses and whose treatment of these masses in bulk requires to be supplemented at all times and in every direction with the highest aid which can be given by modern knowledge. It is not that the general practitioners of the country must be given a chance to work along these lines; it is rather that *unless these are the lines upon which the developments of the future are made medicine will lose the service of the right sort of men.* The idea that there are consultants and officials and some others must entirely disappear out of the theories of education and out of bureaucratic legislation, and the promptitude with which they will so disappear would be remarkable if a real Ministry of Health were instituted in which the conditions of service for the general practitioner were fairly arranged. There must be local consulting centers, facilities for the transport of hospital patients from rural districts, extensive support of bacteriological laboratories as as an adjunct to provincial practice, and real intercommunication between the official and the general practitioners. Unless these things are provided for the Ministry of Health will not minister to health.

A Special Clinical Meeting of the British Medical Association.—The customary annual meeting of the British Medical Association will not take place in 1919, but will be replaced by a special clinical meeting to be held early in April. The annual meetings, which have been suspended for the last four years owing to the war, will be resumed in 1920, the seat of the meeting being Cambridge.

The Vaccines and Serums Supplied to the Royal Navy.—Previous to 1916 the greater part of the vaccines required in the Royal Navy were received from the inoculation department of St. Mary's Hospital, London, under the superintendence of Sir Almroth Wright. But since that date the navy has made itself responsible for its own vaccine-therapy, and vast quantities of vaccines and serums have been prepared in the laboratories of the Royal Naval College at Greenwich by the naval staff. The part played by vaccines and serum in the prevention of disease and the treatment in the Royal Navy is sufficiently indicated by the following summary of quantities prepared, which has been published by Captain P. W. Bassett-Smith, the professor of pathology and lecturer on tropical medicine at Greenwich College: Typhoid vaccine, 5400 c.c. Paratyphoid vaccine, 21,500 c.c. Triple typhoid vaccine (Naval formula), 247,700 c.c. The triple vaccine is a mixture of B. typhosus, paratyphosus "A," and paratyphosus "B" heated to 55 deg. C. for half an hour, 0.5 per cent. phenol is then added. Cholera vaccine, 8600 c.c. (Prepared from several strains of Balkan origin.) Antisepsis vaccine, 48,400 c.c. (A mixed polyvalent vaccine containing streptococci and staphylococci.) Influenza vaccine, 144,000 c.c. (A mixed polyvalent vaccine containing *B. influenzæ*, streptococci, and pneumococci.) Melitensis vaccine, 1380 c.c. Staphylococcic vaccine, 910 c.c. Tetanus antitoxin, 14,800 doses. Diphtheria antitoxin, 2400 doses. Antidysenteric serum, 2800 doses. Antistreptoccic serum, 1250 doses. Antimeningococcic serum, 5000 doses (and others in smaller quantities). Vaccine and serum treatments have their finest opportunities in the Royal Navy. The men are subjected to risk of every conceivable sort from tropical diseases, while the conditions in which they live make concealment of the conditions impossible, and dates of infection certain. Moreover the blue-jacket is an extraordinarily good patient, brave, disciplined, and eminently healthy and wholesome.

8. Some Pathological Conditions of the Mouth and Their Treatment.—Chalmers J. Lyons points out the responsibility that rests with the educated dentist of the present day whose duty it is to make a thorough examination not only of the tooth surfaces, but of the mucous membrane, tongue, tonsils, pharynx, and salivary glands. Although the *x*-ray is indispensable in dental practice, other factors must be considered in arriving at a diagnosis; the pathological must be differentiated from the physiological and the radiograph employed as a further means of reaching a definite conclusion. One of the most perplexing problems met with is that of obscure pain localized in the jaws. Healthy teeth are frequently sacrificed in an endeavor to eliminate a possible source of socalled neuralgia, whereas the real source of the pain may be a paratonsillar abscess or a tooth in the other jaw. Goldscheider has suggested that in the Gasserian ganglion there are certain nerve cells which have either split fibers or two separate nerve fibers, one running in one division of the fifth nerve and the other in one of the other divisions of the same nerve. If the source of infection is in either the second or third division of the fifth nerve, a diagnosis can usually be made by blocking off a section of the branch and observing the results. In regard to tic douloureux, it is contended by many able brain surgeons that its etiology is of central origin. Neither removal of the teeth, nor injections of alcohol, nor even neurectomy offer permanent relief, and in the author's opinion operation on the ganglion itself is the only means of obtaining this. Another type of referred pain is that arising from an old syphilitic lesion. This improves under antisyphilitic treatment. The primary lesion is frequently found on the lip or on the tonsils; seldom on the cheek or tongue. It can be differentiated from certain forms of stomatitis in that the chancre is painless and usually causes enlargement of the lymph nodes. Secondary syphilitic manifestations of the mouth are usually of an erythematous or ulcerative type, commonly seen on the oral pharynx as an in-

flammatory area, attended by little or no pain. Mucous patches may be observed on the edge and tip of the tongue, on the dorsum of the tongue, uvula, and fauces, or on the inner surface of the lips. They are irregular patches of greyish white color, covered by a sticky secretion and may be differentiated from other lesions in that they are unaccompanied by pain. Gummatous ulcers in the mouth—tertiary syphilis manifestations—may be mistaken for carcinoma. On the tongue they usually appear over the whole upper surface, whereas carcinoma would be confined to the edge or one side of the tongue. Carcinoma, however, frequently supervenes on an old syphilitic lesion. In all cases suspected of syphilis, nothing should be done until a Wassermann test has been made. Leucoplakia is a precancerous condition which is invariably caused by excessive use of tobacco. The similarity between leucoplakia and secondary syphilis is often confusing. Syphilitic plaques usually appear on the border and back of the tongue and at the same time other patches may be observed on the gingiva, palate, or tonsils. They are soft, whereas those of leucoplakia are hard. Since the dentist has opportunity of observing precancerous conditions long before the physician sees the patient—when it is frequently too late to eradicate the disease—it is the duty of the dentist to direct the patient's attention to such conditions and, if possible, to have a microscopical examination made. Dentigerous cysts are frequently seen in the mouths of men and women under thirty, and may be mistaken for a tumor or an alveolar abscess. They may be differentiated from an osteoma since fluctuation and crepitation can usually be elicited. They differ from alveolar abscess in that they are very slow in formation and not accompanied by pain. These cysts should be widely opened and the unerupted tooth or tooth follicles and the cystic lining removed. The author has obtained good results from packing the cavity with iodoform gauze and irrigating with five per cent. salt solution every twenty-four hours. Absorption of bone is the most serious sequela. Epulis occurs frequently in childhood and in young adults, and is more common in women. There are two varieties—the fibrous and the giant cell, the latter being the more frequent. Growth is slow at first but becomes rapid as the tumor progresses, causing the teeth to spread apart with consequent loosening. The tumors, which remain attached to a small stalk, are benign at first but later become malignant. They should be removed as soon as identified, and examined microscopically. The portion of the periosteum or alveolar process to which they are attached should also be removed, and actual cautery employed to sere over the wound. Another important and not infrequent pathological condition of the mouth is Vincent's angina, which is characterized by a deep tissue necrosis, covered by a whitish grey membrane. This membrane is easily removed and when rubbed off leaves a granular, raw, bleeding base, which leads to craterlike ulcers with irregular edges. The condition is infectious but prognosis is usually favorable and if seen early, these cases can be easily controlled. In disease of the antrum of Highmore, the author believes that closer cooperation between the dentist and the rhinologist is needed. Three principles must be kept in mind in the treatment of empyema of the antrum: the source of irritation must be removed, drainage must be established, and ventilation must be maintained. A correct diagnosis is of the utmost importance, as it is essential that the source of irritation be removed or the opening will not close. The author then turns to morbid conditions involving the pericemental membrane. The difficulty here is to decide whether to extract the tooth or to perform root resection. This again is largely a question of diagnosis. The health, age, and recuperative force of the patient must be considered, as well as the condition of the blood supply to the apical area; that is, it must be decided in each individual case whether or not conditions are favorable to normal repair of bone. The proper evaluation of *x*-ray findings is of great importance. If the case is one of alveolar abscess of long standing, or a case of imperfectly filled root canal with granuloma showing in the apical area, surgical procedure is indicated. Before root resection is done, a crown or bridge attachment should be removed, the canals and dental tubules thoroughly sterilized and the canals filled; otherwise reinfection will occur. Sterilizing and completely filling canals in multirooted teeth for the eradication of an infection the author considers a doubtful procedure, believing that the patient's welfare would be better safeguarded by extraction followed by curettage of bone. This operation should not be resorted to when the bone and pericemental membrane are diseased beyond the apical third of the root.

5. Slow Intravenous Injection of Antiserum to Prevent Acute Anaphylactic Shock.—Julian H. Lewis reviews the various methods tried from time to time in an effort to prevent anaphylactic shock. The use of hypertonic salt solution was found to diminish anaphylactic shock in animals but there are no reports of the use of this procedure in man. The methods usually employed are those worked out by Besredka, namely, the administration of minute single or repeated doses of antigen three or four hours before the full injection is given, or the rectal injection of from 5 to 10 c.c. of serum, when gradual absorption of antigen occurs. Another method, suggested by Friedberger & Mita, is that of slow administration rather than division of dose. It having been shown that the danger of serum sickness was influenced by the size of the dose, the logical procedure was the production of antiserums with a higher concentration of antibodies. But though it was possible—particularly in diphtheria—to give large doses of antibodies in a small volume and thus lower the severity of anaphylaxis, serum sickness was not prevented. In the case of pneumonia, the concentration of antibodies has not been successfully accomplished and furthermore the promulgators of the use of antipneumonic serum advise the direct intravenous injection of doses as large as from 50 to 100 c.c. These two factors no doubt are responsible for the serious anaphylaxis reactions reported from army camps. The author believes that the slow protracted injections of diluted serum, as advocated by Friedberger and Mita, is the method best adapted to the conditions, particularly if the Woodyatt pump is employed. The results of animal experimentation have led him to the following conclusions: That acute anaphylactic shock can be prevented in sensitized experimental animals by giving otherwise fatal doses of diluted antigen intravenously at very slow rates. That so far as these results can be applied to man, it is to be recommended that when immune serum must be given intravenously, it should be given slowly and in a diluted form, the Woodyatt pump serving as an excellent means of doing so. The exact quantitative relations must be worked out experimentally with patients. At present it can only be said that the injections should be made as slowly and the dilutions should be as high as is convenient or necessary under a given set of conditions.

8. Empyema Following Influenzal Pneumonia.—Major Max Ballin gives the results of his observations on the epidemic which occurred at Camp Grant, Ill., in September and October last. He points out that in the treatment of empyema it is necessary to differentiate between three types: (1) The empyema following hemolytic streptococcus infection, which occurs early as an exudate in the first week of the pneumonic process, is thin, very copious, and capable of being absorbed, and should be handled, if necessary to relieve pressure, with aspiration, operating by costectomy only after the pneumonia has subsided. (2) The empyema following lobar pneumonia. This sets in four weeks

after pneumonia, is of good prognosis, and can safely be handled with costectomy. (3) The empyema following influenzal pneumonia. This also develops four weeks from the onset of the process. On account of serious and frequent metastatic suppuration, its prognosis is more severe than that of form 2. It is best handled by thorough drainage, by costectomy under local anesthesia. Major Ballin emphasizes the importance of local anesthesia in operations for empyema, in view of the frequency of sudden death from suffocation under general anesthesia. He describes the technique of the operation and states that of seventy-nine patients operated upon eleven died, all of whom, however, had severe complications. The first thirty patients were treated with neutral solution of chlorinated soda, every attention being paid to the details of administration, and of this group eight died. The remaining forty-nine patients were given dry treatment, with three deaths.

4. Meningococcus Bronchopneumonia in Influenza.—Captain William Fletcher submits the results of a study of 36 fatal cases of bronchopneumonia which occurred in American soldiers, in 11 of which Pfeiffer's bacillus was found in association with the meningococcus. The other cases were due to combined infection with this bacillus and pneumococci or streptococci. Beyond possibly a greater tendency to hemoptysis, there were no clinical signs to distinguish the cases of meningococcus bronchopneumonia. None showed any signs of meningitis before or after death. Summarizing these cases, the author states that: (1) In the postmortem examination of 36 men who had died from bronchopneumonia following influenza, Gram negative cocci were the predominant organisms found in the lungs of 11 cases. (2) All the men, with one exception, had been taken ill on board the same transport. (3) In six cases these Gram-negative cocci were Type II meningococci and in one case they belonged to Type I. In four instances the cocci were not tested by agglutination. (4) In each of the 11 cases Pfeiffer's bacillus was found in symbiosis with the Gram-negative cocci. (5) The meningococcus, like other "respiratory" organisms, may, when it occurs in conjunction with Pfeiffer's bacillus, produce a fatal bronchopneumonia.

4. Note on a Case of Acute Febrile Polyneuritis.—R. W. Dale Hewson and R. M. Stewart report a case of acute febrile polyneuritis which, as far as the authors are aware, is the first that occurred in the British Salonica force. The symptoms exhibited conformed closely to those described by Holmes in the cases that occurred in France. The sudden onset of illness in a healthy man with feeling of malaise and slight fever, but no shivering, vomiting, sweating, or other symptoms characteristic of malaria, the rapidly developing flaccid motor paralysis, the implication of certain cranial nerves, the early loss of sphincter control, and the relatively insignificant sensory changes. The lower limbs showed a marked degree of paralysis, but no individual movement was impossible, nor were the distal segments of the limbs more paretic than the proximal. Muscular atrophy occurred to a very slight degree. The muscles of the upper limbs were much less severely affected. No affection of the intercostal or abdominal muscles was noted. Complete paralysis of all muscles innervated by the seventh cranial nerves was observed on the third day of the patient's illness, and formed a striking feature of the clinical picture. Articulation was slurred and indistinct. Neither the tongue nor the palate was involved, but the patient experienced difficulty in swallowing. There was no involvement of the muscles of mastication, and phonation was unaffected. The reactions of the pupils were normal, but paresis of the left external rectus was noted, and the patient complained of occasional double vision. Cutaneous sensory disturbance was very slight. At first slowness of perception of tactile and painful stimuli was noted, and at a later date a raised threshold for the appreciation of simultaneously applied compass points. Joint sense and vibration "sense" were apparently normal. The abdominal and plantar reflexes were absent; also the deep reflexes (except the triceps jerks). Incontinence of feces existed for two days. There was no disorder of mental functions. Definite improvement was noted twelve days after the onset of the symptoms. Examination of blood, the cerebrospinal fluid, and the urine yielded negative results. It remains to be noted that in one or two particulars the patient did not conform to the usual clinical features. While sphincter trouble was very transient, the difficulty in swallowing persisted up to the time of the patient's evacuation from Macedonia. Paralysis of the diaphragm, not hitherto recorded, was present in this case. The proprioceptive forms of sensation, which are said to be frequently involved, were unaffected. Although a typical malarial attack occurred on the twenty-first day of illness, the parasite of benign tertian fever being demonstrated in the blood, the authors are of opinion that this fact furnishes no conclusive proof that the case reported was conditioned by the malaria toxin. There was no history suggestive of malaria, nor was the parasite found until the patient had been three weeks in hospital. Moreover, a differential blood count gave normal results. The authors, however, base their opinion chiefly upon the fact that in cases of post-malarial multiple neuritis that have come under their observation, the clinical features have been very different from those described in the case reported. The recent occurrence of a variety of polioencephalitis in epidemic form in the British Isles suggests the presence of some such pathological basis, but the complete integrity of the mental functions and the clinical course of the symptoms observed in this case, renders such an etiology extremely unlikely.

Berliner klinische Wochenschrift.

December 2, 1918.

The Serum Treatment of Diphtheria.—A. Czerny sums up the present state of uncertainty regarding the real value of the serotherapeutic treatment of diphtheria since Bingel declared, with statistics to back him, that the action of simple horse's serum was equal to that of prepared horse's serum. The recent discoveries on the curative action of albumins injected in the muscles or veins would seem, in fact, to divide the efficacy of antidiphtheritic serum between serum albumin and antitoxin properly speaking. However, until more extended experimentation, there is no reason for changing the classic treatment of diphtheria with specific serum in any way.

The Forms of Septicemia Due to the Bacillus of Tuberculosis, the Typhobacillosis of Landouzy, and Miliary Tuberculosis.—M. Scholz brings forward to illustrate this still much debated subject an interesting case. The patient, a woman fifty-six years of age, ill for three weeks with a symptomatology entering into

the typhoid class, without, however, showing any roseola. The sterility of the blood led the writer to conclude that the case was one of miliary tuberculosis. At autopsy there were no granulations visible macroscopically and only the usual pathological changes of a septicemia were noted, but microscopically small foci of necrosis containing acid-resistant bacilli were discovered in the liver, spleen, and other viscera. Scholz states that this clinical observation would be placed in the class of Landouzy's typhobacillosis; however, he refuses to regard this as a form of disease and prefers to call it superacute tuberculous septicemia. He points out that the anatomic status does not differ from the classic miliary form other than by an absence of granulations and that this difference is the result of the reactivity of the patient and that therefore it should not be transferred from the general class of miliary tuberculosis. The possibility of such septicemic varities with a mild evolution, such as Landouzy describes, cannot be entertained according to the writer's view, since the absence of miliary granulations should be regarded as improper for maintaining this theory. A rather complete bibliography is appended.

Münchener medizinische Wochenschrift.

November 26, 1918.

The Functions of the Human Appendix.—K. Peter desires to oppose the tendency to look upon the appendix as a rudimentary organ of no use. A foundation of value for the assertion that this organ is useless cannot be found either in comparative anatomy or embryology. From its structure the appendix belongs to the group of lymphoepithelial organs and therefore is similar to the thymus, tonsils, etc. (a fact known for the past thirty years or more but coming from Germany it must be new). Although recognizing that removal of the organ does not unfavorably influence the general health, Peter attributes a function to the appendix which is as yet enigmatical.

The Prevention of the Phenomena of Hypersensibility in the Parenteral Exhibition of Heterospecific Albumin.—E. Friedberger, well known for his theories relating to anaphylaxis, recalls the procedure of small doses employed with the object of preventing anaphylactic reactions when giving animal sera. This procedure of sensibilization attains the maximum of its efficacy when the injections are given as progressively in amount as possible. The writer describes a simple form of syringe which permits giving a slow, graded injection. Experimental researches have shown that his manner of procedure allows one to go far beyond the ordinary fatal dose to the extent of twenty times its strength in sensibilized animals.

The Triceps Muscle Used as a Motor Force in Prostheses.—H. Böhm studies the deformity produced by transversal section in an amputation stump when the triceps contracts. This change can be utilized for transmitting, by means of a pulley, traction in the direction of the axis of the arm and this mobilizes the parts composing the prosthesis. In the same way the movement of rotation of the humerus in the axis of the arm can be utilized for accomplishing movements of pronation and supination in the artificial limb. The writer gives a figure showing the mechanism of the principles laid down.

Deutsche medizinische Wochenschrift.

November 28, 1918.

Silver-Sodium Salvarsan.—Galewsky gives a favorable report on this product, put on the market by the bacteriologist Kolle, which accords with the writers on the subject already noted in these abstracts. The product possesses an energetic action in much smaller doses than required by neosalvarsan. The writer is of the opinion that this higher efficiency is due to the combination of metallic silver with the salvarsan radicle and that it results that Kolle's product avoids the dangers of intensive arsenical treatment while assuring the same therapeutic effects. The most evident results are obtained in luetic manifestations on the mucosæ, either of the secondary or tertiary types. The product, like Ehrlich's original 606, is patented and the numerous articles describing it are evidently in the nature of advertisements.

The Serum Treatment of Influenza.—E. Reiss has injected various sera in influenza patients, such as normal human serum, serum obtained from those convalescing from the grippe, normal horse serum, antidiphtheritic serum, etc. Generally speaking, the writer noted a marked improvement following these injections at the end of thirty-six hours. The best results were obtained with the serum of convalescents and normal horse serum. The writer is of the opinion that the good results are due to a general action of the serum as a blood serum *per se*, rather than to a specific action.

Variola Without Exanthema.—Kathe insists upon the importance of these cases from the viewpoint of epidemiology, and relates some recent experiences. The cases observed by the writer offered a rise in temperature and general signs common to variola. Out of a total of five cases only one offered an eruption which was characteristic of the disease and therefore gave the clue to the real condition of affairs, the other four patients going through their variola without an exanthema or pustules. The writer attributes this mild evolution to vaccination which all soldiers had received at the beginning of the war. From the viewpoint of contagion it goes without saying that these patients are quite as dangerous, even more so, than frank cases on account of the possibility of overlooking the correct diagnosis.

Le Progrès Médical.

Intravenous Injections of Camphorated Oil in the Asphyxiating Types of Grippe.—Loeper and Fumouze do not include pneumonic forms under this head. In the type referred to the patient is stricken in the midst of apparent health with fever which is not as high as a rule as in pneumonias. The skin is very pale, excepting where cyanosis is present and severe dyspnea is prominent of a form suggesting uremia. The physical signs do not reveal any one focus of disease in the lungs, but the râles heard everywhere suggest congestion and edema. Expectoration is scanty, but hemoptyses sometimes occur. This does not always mean that there is no secretion in the air passages, for some patients are unable to rise and are suffocated by their own secretions. The heart is weak and dilated and its action very rapid. Seven autopsies agreed in showing a mixture of infarcts, congestion, and edema with absence of pneumonic foci. As a rule albuminuria was present and acute uremia was thought of, but examination of the blood showed absence of retention of urea. The whole picture suggests an intoxication of unknown character which attacks the bulbo-vagus system. The untreated patients with these forms have invariably perished in two or three days. Next to the thoracic organs the nerve centers suffer, as delirium and mental confusion are usually present. The treatment of these cases must be heroic and consist of venesection with infusion of adrenalized serum and camphorated oil injected into the venous system. The authors have with this treatment cured twenty out of thirty-eight cases, which in a disease of 100 per cent. mortality is very satisfactory. The amount of camphor injected is 2 c.c. of a 10 per cent. solution daily throughout the course of the disease. The immediate effects are very striking, as the entire disease picture improves promptly.

Minor Forms of Graves' Disease.—Lian discusses this much described syndrome, apparently because it is still far from being clarified. If a subject have palpitation and tachycardia has he an abortive form of Graves' disease? The question is a delicate one to decide. We have no biologic reaction to settle it and must depend on resources of some sort to differentiate between this and other forms of tachycardia. Paroxysmal attacks are at once excluded as far as the latter is concerned, for there must be a permanent acceleration of the heart

beat beginning at 100 and we must exclude a number of organic diseases, whether cardiac, renal, tuberculous, etc. We know that in Graves' disease the tachycardia may be very slight while in pure neuropathy it may be rapid. Morning tachycardia suggests Graves'—*i. e.* tachycardia which is more marked in the first part of the day. Blood pressure studies seem to be of no value in differentiation for in both Graves' and neuropathy it is somewhat elevated. Radiographers have recently claimed the existence of aortic dilatation in Graves' disease, but this has been found to be inconstant. As for the great number of neurotic manifestations they are of no diagnostic value, all being common in essential neurasthenia. Moreover the association between a goitre and tachycardia may be purely fortuitous. The author has written his paper to bring out the significance of a new symptom—hyperesthesia over the thyroid region. This the author has noted in some ten cases and his attention was attracted to it as a result of palpatation of the thyroid for enlargement. In three of these there was enough outside evidence to make the diagnosis but in the balance it is doubtful if any diagnosis could be made unless the value of this sign is acknowledged. This hyperesthesia is not of the type which one would ordinarily have in mind but an increased sensitiveness to pain. Slight manipulations call forth grimaces of discomfort. In the typical case this area is limited to the gland. That the sign is a new one seems evident from the frequency of the statement that the goitre in this affection is insensitive. The sensitiveness is in all probability due directly to an increase in tension of the enlarging gland. The author recommends that in routine examination of the thyroid in obscure affections particular attention should be paid to undue sensitiveness of the organ.

The Three Clinical Types of the Current Epidemic.—Sofre does not refer to the time honored division of influenza into respiratory, intestinal, and nervous types. On the contrary, his division pertains only to the respiratory type and the degrees of severity of it. The first type isolated is the febrile, in which fever is the dominant symptom. This is the usual type and the benign type. The disease has no special localizations, and therefore when such coexist the author makes a second type. The third type is the malignant, or septic. The simple febrile type exhibits a localization in the respiratory apparatus, but this is not a local expression of the disease in the author's sense. Among the latter are the bronchopneumonias, nephrites, etc. The socalled enteric forms also belong here. A special characteristic of these localizations is the tendency to hemorrhage in all. Thus we see nosebleed and melena which suggest typhoid fever, hemorrhagic nephritis, etc. The malignant type, in addition to profound septic and toxic manifestations, is characterized by unmotivated dyspnea. One would imagine that the lungs were the seat of profound lesions, but examination reveals a surprising state of affairs, to wit, absence of anything which could explain this dyspnea. While in the second form with pulmonary location we find classic bronchopneumonia but no unusual dyspnea or toxemia; in the third type the lungs seem quite clear. Not one case of this toxic type can recover. Hence the extreme dyspnea can only indicate the presence of a pseudobronchopneumonia. To explain, the author believes that two factors are necessary, the toxemia due to bacillemia and the involvement of the kidneys—in other words, a species of uremic dyspnea. The nephritis in these cases is secondary to sepsis and apparently not due to a special localization of the disease in the kidney.

November, 1918.

New Experiences in the Treatment of Hemoptysis.—Lunde refers to this complication of pulmonary tuberculosis as studied in sanatoria. A hemorrhage from the lungs causes lively apprehension to both the patient and his entourage and some equally heroic medication seems called for. But these attacks usually cease spontaneously through the formation of thrombokinase. The cases which do not thus improve call for urgent treatment. Left to themselves some patients bleed for days, or hemorrhages continue to succeed one another at intervals. Very slight causes may start these bleedings—a slight exertion or perhaps the focal reaction from a tuberculin injection. One may follow running upstairs. In all such cases it is natural to believe that a strong predisposition is furnished by the presence of an eroded vessel in a cavity wall, by the softening of a disease focus or similar cause. While the blood pressure in tuberculosis is commonly said to be subnormal it is a fact that for a hemorrhage to occur the pressure should be high. Air pressure changes in the thorax probably play a subordinate rôle. Among the consequences of hemoptysis are aspiration pneumonia and extension of the tuberculous process. Death from acute anemia is very rare but death from aspiration of large amounts of blood is not so rare. Finally anemia is a more remote consequence. The author enumerates the standard remedial procedures and then observes that one of these renders the others largely superfluous—injection of large doses of camphorated oil. Of 22 cases of hemoptysis seen in the past year 13 required no special treatment while in the other 9 who had medium or large hemorrhages—from 40 to 400 grams—arrest was at once obtained by injection of 3 cm. of 20 per cent. camphor-oil.

Correspondenz-Blatt für Schweizer Aerzte.

Malignant Growths Which Begin with Leucemia.—Munk distinguishes between leucemia as a disease of the hematopoietic system, in which the blood making organs develop hyperplastic changes and leucemia associated with malignant tumors. There are at least three forms of the latter, lymphosarcoma, myeloma, and chloroma. In recent years attempts have been made to incorporate other neoplasms with the latter. These are covered by the general term leucosarcomatosis. The conception of leucosarcoma is due chiefly to Sternberg, who described a number of cases. At its outset leucosarcoma consists rather of tumor-like tissue than actual tumors, and hence seems a connecting link between pure leucemia on the one hand and the malignant tumor form on the other. While a few men have accepted Sternberg's theories and have reported cases of his leucosarcoma many others refuse to accept them on four counts. First, in simple leucemias we may find evidence in a small way of processes analogous to leucosarcoma. Again the size of the cell in leucemia is not an absolute criterion, for the typical small-cell leucemia may shade into forms with larger cells. Thus in a typical small-cell lymphatic leucemia Strauss found sarcomatous tissue in the thorax, lungs, and lymphatics. In an entire series of cases it has been shown that in clinical and microscopical simple leucemia tumor-like tissue has been discovered—therefore there is no sharp differentiation between the simple and Sternberg types of leucemia. From another angle the Sternberg leucosarcoma has in certain cases been pronounced no different from lymphosarcoma. Also the tumor-like proliferation in the Sternberg type has been declared as unlike true tumor growth, so that confusion could hardly go further. Nothing can be predicated of large-cell lymphatic leucemia that may not be true of the small cell form. Each may exhibit so-called aggressiveness under certain conditions. Attempts to connect blood pictures with tumor formation seem doomed to failure. The malignancy of certain individual cases seems an unmotivated epiphenomenon. The author, who started to give four arguments against Sternberg's theories, does not state the other three, evidently leaving the reader to find them out.

Cure of Mikulicz's Disease with Neosalvarsan.—Massary and Tockmann cured a classical case of Mikulicz's syndrome of presumably syphilitic origin by injections of neosalvarsan and mercury biniodide. The condition of the parotids was inflammatory while the lacrymal glands presented rather an hypertrophy.—*Le Progrès Médical.*

Book Reviews.

GLAUCOMA. A Textbook for the Student of Ophthalmology. By ROBERT HENRY ELLIOT, M.D., B.S. (Lond.), Sc.D. (Edin.), F.R.C.S. (Eng.), etc.; Lieut.-Colonel I. M. S. (Retired); Late Superintendent of The Government Ophthalmic Hospital, Madras; Late Professor of Ophthalmology, Medical College, Madras, and Late Fellow of the University of Madras; Honorary Fellow of the American Academy of Ophthalmology and Otolaryngology. With 155 illustrations. Price, $7.50. New York: Paul B. Hoeber, 1918.

COLONEL ELLIOT has a high reputation as an authority on the eye and its affections and abnormalities, and therefore a book from his pen is always welcomed by all ophthalmologists. Appreciating the fact that a great deal of ignorance existed with regard to glaucoma, for a period of three years he has made a special study of the subject, earnestly endeavoring to sift the chaff from the wheat and to place the knowledge of glaucoma on a sound and scientific basis. The author seems to have succeeded well in his self-appointed task, and the views expressed by him on the value of sclero-corneal trephining are as original and interesting as ever. The question of glaucoma is thoroughly considered, the book is well illustrated, and is a valuable addition to the literature of ophthalmology.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS. By JOSEPH B. DE LEE, A.M., M.D., Professor of Obstetrics at the Northwestern University Medical School; Obstetrician to the Chicago Lying-in Hospital and Dispensary, and to Mercy Hospital; Consulting Obstetrician to Provident and Evanston Hospital, etc. With 949 illustrations, 187 of them in colors. Third Edition. Thoroughly Revised. Price, $8.50. Philadelphia and London: W. B. Saunders Company, 1918.

THIS is an eminently practical work on obstetrics. It is practical not only because it is written and compiled by a practical obstetrician, but because it is from the pen of a teacher of obstetrics who is well acquainted with the needs of the medical practitioner and student in this direction. While the ultimate object of a good text-book on obstetrics is always kept in view, that of enabling the reader in search of practical information to gather it without difficulty, the scientific part of the subject is not neglected. All this mass of matter is condensed as much as possible in view of the fact that the student's curriculum is already overcrowded. Conciseness and brevity, as far as compatible with an adequate consideration of obstetrics in all its detail, are followed. The result is highly satisfactory. However, as this is a third edition, it will be superfluous to dwell upon its features except to say that it has been thoroughly revised. The illustrations serve well to elucidate the text. The book may be commended to the attention of practitioners and students.

THE HEARTS OF MAN. By R. M. WILSON, M.B.; Late Assistant to Sir James Mackenzie, under the Medical Research Committee. New York: Oxford University Press, American Branch, 1918.

KNOWLEDGE concerning the heart and its mode of action is increasing continually and to Sir James Mackenzie is due a great deal of the credit for rendering the acquirement of this knowledge possible. Mr. Wilson, the writer of this book, was assistant to Sir James, who together with Professor Bayliss read through the manuscript and offered certain criticisms. The author has some original ideas as to the action of the heart which are well worthy of study by the physician. The book is highly interesting and no doubt will be widely read by medical practitioners, and especially by those who have made a study of the circulatory system.

ON THE NATURE OF THINGS. By HUGH WOODS, M.D., B.A., F.C.S.; Author of "Ether: Its Nature and Place in the Universe." New York: William Wood & Company, 1918.

THIS is a book which explains in clear language the meaning of matter, space, motion, and time, and shows how all physical science can be built up without assuming the existence of more than these and modifications of them. It is a very interesting bit of reasoning in the domain of physics and does what all books unfortunately do not—what, in fact, few books do—it sets the reader thinking.

A MANUAL OF PHYSIOLOGY. With Practical Exercises. By G. N. STEWART, M.A., D.Sc., M.D. (Edin.), D.P.H. (Camb.); Professor of Experimental Medicine in Western Reserve University; Clinical Physiologist to Lakeside Hospital, Cleveland; formerly Professor of Physiology in the University of Chicago; Professor of Physiology in the Western Reserve University; George Henry Lewes Student; Examiner in Physiology in the University of Aberdeen; Senior Demonstrator of Physiology in the Owens College, Victoria University, etc. With colored plate and 492 other illustrations. Eighth Edition. University Series. Price, $5.00 net. New York: William Wood & Company, 1918.

THE place of Stewart's book in the realm of physiology has been established long since and the reviewer of the eighth edition finds little to add except to note the revisions made. These, on account of the war, have not been very extensive, as war always means a pause in laboratory activities. If we assume that a reviewer must find some fault, no matter how slight, we might express a preference for the practical exercises interspersed in the text rather than at the end of chapters. Dr. Stewart's conception of the function of the endocrine glands is considerably at variance with the ideas of Cannon. His accounts of the circulating fluids, blood and lymph, are excellent, probably the best to be found in any book in the English language. Altogether the book is an admirable text-book of physiology and contains an immense amount of information without being too bulky.

SYPHILIS, PALUDISME, AMIBIASIS; Traitement Initial et Cure de Blanchiment. Par PAUL RAVAUT. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1918.

THIS little volume contains a preface by Professor F. Widal, the well-known clinician. The parasites of all three of the diseases mentioned are protozoans, and remedies known to act specifically on the latter are quinine, arsenic, and emetine. The three remedies can be combined with one another in such way as to increase their potency—quinine and arsenic in malaria, emetine and arsenic in amebic dysentery. The "bleaching cure" mentioned by the author has apparently the same significance as "sterilisatio magna," and denotes the destructive action of the medicaments on the protozoan parasites. The volume is eminently a product of war medicine, for the troops have been ravaged by all three maladies and the treatment is based on the experience of military men in dealing successfully with these patients.

VACCINES AND SERA IN MILITARY AND CIVILIAN PRACTICE. By A. GEOFFREY SHERA (Hon. Capt., R.A.M.C.), with an Introduction by Sir CLIFFORD ALLBUTT, K.C.B., M.D., F.R.S. Oxford War Primers. Price, $2.50. New York: Oxford University Press, American Branch, 1918.

THE subject matter in this work comprises a voluminous chapter on vaccines and one of about half the bulk on sera; a third section is devoted to specific therapy of diseases of women and children, while a fourth cleans up outlying matter. Vaccines, whether prophylactic or curative, and sera, grouped in the same manner, are subdivided according to dependability into several categories. This is the most conspicuous and characteristic feature of the work, which is eminently practical. To assist the reader in this particular there is a general summary on page 196, which enables him at a glance to decide as to indications for therapy or prophylaxis in a given case. A feature which is less commendable is the classification under one head of severe and indifferent affections. From the clinical side it would seem more efficient to distinguish between lethal and banal affections. This distinction is radical throughout. The subject of an acute and virulent, for example, requires perhaps heroic treatment, while the victim of something no more serious than acne or even boils may be treated over a long period of time in a most conservative fashion.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

Thirty-first Annual Session, Held at Baltimore, December 17, 18, and 19, 1918.

THE PRESIDENT, DR. ISAAC S. STONE, OF WASHINGTON, D. C., IN THE CHAIR.

Suture of Ruptured Kidney, with Report of a Case.—Dr. S. L. LEDBETTER, JR., of Birmingham, Ala., said that an early exploration was indicated in subparietal injury to the kidney and suturing the ruptured kidney where possible was preferable to either nephrectomy or gauze packing. Nephrectomy should be reserved for those cases where operation had been delayed and when the kidney was hopelessly damaged. Packing with gauze, where possible, was to be avoided on account of the delayed convalescence, the danger of secondary hemorrhage, and the possibility of infection. Connell had collected sixteen cases of suture of ruptured kidney with two failures, one developing a urinary fistula and the other requiring secondary nephrectomy. He reported the following case: Negro, male, age twenty-four, fell from a scaffolding, striking his right flank against an iron casting. He was seen shortly afterward and, though somewhat shocked, was in good condition. All evidence pointed to an injury of the right kidney without associated injuries. Exploring the kidney twelve hours later, an extensive transverse rupture was found between the middle and lower thirds. This was sutured with chromic catgut, a small cigarette drain inserted down to the capsule and the wound closed. The patient made an uneventful recovery, and on leaving the hospital nineteen days later the urine showed only an occasional blood cell. Subsequent specimens were normal and he understood that the patient was now in army service.

Prostatectomy, with Its Preparatory and Postoperative Treatment.—Dr. BRANSFORD LEWIS of St. Louis stated that after considerable experience with the removal of the prostate by the suprapubic and perineal routes, he had adopted the suprapubic method as the one of choice because it gave the better results. It was free from a number of momentous objections that pertained to the perineal operation, such as ineffectual urinary control, sexual disability, urethrorectal fistula, etc. While a one-stage suprapubic prostatectomy might with confidence and safety be carried out in a patient of middle age and good general condition, there was no doubt about the marked and distinct advantages presented by the same operation done in two stages in the decrepit patient of advanced years, and weakened resisting powers. The opportunity presented by the two-stage operation of establishing a firm adhesion between bladder and abdominal walls was scarcely less valuable than that of establishing suprapubic drainage. Infection of the loose connective tissues surrounding the bladder and extensive suppuration in these cases was one of the most serious dangers attendant on suprapubic work. Once established, such suppuration was difficult to control, and the condition might rapidly become formidable. The ounce of prevention consisted in attaching the bladder firmly and permanently to the abdominal wall around the opening in the bladder by means of chromicized catgut sutures. Spinal anesthesia was commended as serviceable by some operators, but he regarded it as the most dangerous of all methods of anesthesia. His personal acquaintance with some seven or eight instances in which death was attributed directly to spinal anesthesia used by operators well versed in its technique had led him to this conclusion. He knew of no death so far reported from the use of caudal anesthesia, although there had been instances in which physiological effects had been observed.

Dr. JOHN R. WATHEN of Louisville heartily agreed with the essayist that the main thing in prostatic surgery was proper drainage and the avoidance of infection. He disagreed with him, however, when he made the statement that the indwelling catheter should remain in the urethra a considerable time, even nine months, as he mentioned in one case, because his experience had been that the indwelling catheter was not tolerated by the majority of patients for a considerable time, and some patients could hardly stand it at all. He believed the suprapubic operation under local anesthesia was the operation of choice.

Dr. ROBERT T. MORRIS of New York City stated that after the suprapubic operation he liked to fold the ragged fragments into place pretty well and pack them there with neat folds of iodoform gauze, leaving the end of the gauze protruding from the suprapubic wound, and for drainage he used little packs of sphagnum moss, allowing the patient to turn on one side or the other or abdomen if he liked, and he depended upon the capillarity of the gauze and sphagnum moss.

Dr. FRANCIS REDER of St. Louis said that a mortality following prostatectomy rested with the loss of blood. It was the constant bleeding in these cases that caused fatalities, and in the after-treatment of cases of prostatectomy he could heartly recommend the use of the Hagner bag for the control of hemorrhage.

Dr. JAMES E. THOMPSON of Galveston stated that Dr. Lewis left out one of the most important tests we had that would give us a clear idea as to how patients behaved after operative procedures. The value of the hemoglobin percentage was great, as was also the phthalein output, but a valuable test was the estimation of the blood urea.

Dr. GEORGE A. HENDON of Louisville said that in suprapubic prostatectomy it was his practice to pack the cavity lightly from which the prostate had been removed with iodoform gauze or plain gauze, and allow the ends to protrude from the suprapubic incision; but before doing so he put an ordinary Nelaton catheter in the bladder. The first twenty-four hours a lot of clots might form, but by irrigating with six or twelve ounces of warm boric acid solution, the lumen of the catheter was kept open and no clot formed, and all drainage took place through the catheter in the urethra, and that was collected by a urinal between the patient's legs. On the third day he removed the gauze packing and all the drainage took place below through the natural way. He had not had any suppuration or hemorrhages to make him dissatisfied with this method of treatment.

Irritable Bladder in Women.—Dr. CHARLES A. L. REED of Cincinnati said that irritable bladder was characterized by frequent desire to urinate, pain in the bladder often extending to the rectum and perineum, sleeplessness, and nervousness, all in a history of long duration and obstinate resistance to all treatment. The causes of irritable bladder were found outside of the bladder and inside of it. Those that were outside of it embraced pregnancy, uterine displacements, infections of the uterine appendages, ovarian tumors, displacement of the intestines and adhesions. Those that were inside of the bladder were gonorrheal and other infections, tumors, calculi, and ulcers. Among the various forms of ulcers the one which was described as punctate was the most important as being probably responsible for the majority of all intractable cases of irritable bladder. It was a small round ulcer about 2 to 3 mm. in diameter, a few being somewhat elongated. It formed in myriad numbers over an area of from 2 to 6 cm. long and from 1 to 4 cm. broad on the front wall and vertex of the bladder. The underlying pathology was that of chronic interstitial cystitis with static edema, causing macular necrosis of the epithelium. The pathology of the condition and the function of the bladder combined to make the condition incurable by so-called conservative means, as demonstrated by ample experience. The diagnosis could be made only by careful consideration of the history, the presence of occult blood in the urine and cystoscopic examination which should be made in all cases of chronic irritable bladder. The only rational treatment was by excision of the ulcer-bearing area. Three successful cases were reported. Thirty-eight of these cases now on record proved that it was a surgically safe procedure and one by which many, probably the majority, of these sufferers could be permanently cured. The conclusions reached were: "(1) The punctate ulcer of the bladder with its associated pathology is a demonstrated clinical entity. (2) The condition, by virtue of the pathology, is not only chronic, but incurable by so-called conservative methods. (3) The usual limita-

tion of the ulcerative process to the anterior wall and vertex of the bladder make it surgically accessible. (4) The treatment by excision of the ulcer-bearing area is justified by its demonstrated practicability and by its equally demonstrated results."

Dr. Guy Leroy Hunner of Baltimore said it was important to remember the conditions in the urethra that might cause symptoms of irritable bladder. He presented a paper at Louisville before the association in which he called attention to cases of chronic urethritis due to chronic tonsillitis, and he had had many opportunities since then to find that the observations made at that time were correct, and that many of the cases of irritable bladder could be cured by finding the focus of infection and removing it.

Dr. Bransford Lewis of St. Louis noted that Dr. Reed had omitted to accentuate one sort of trouble that to his mind was very frequent and very important, namely, irritable urethra in which the irritability was kept up for from five to twenty years or more, and it was not due to any other cause. There was either a spasmodic contracture or organic contracture which was definitely demonstrable, and this condition was relievable by frequent applications to the irritable urethra.

Dr. Reed, in closing, stated that one thing that had been largely overlooked in the urethra very frequently was the involvement of Skene's follicles, to which Skene called attention thirty years ago, and this condition could be relieved by simple intervention.

A Gauze Sponge Spontaneously Expelled from the Urinary Bladder.—Dr. G. Paul Laroque of Richmond, Va., said that five years ago a woman was operated upon in a city near her home in North Carolina and was told that the appendix and left ovary were removed and the uterus suspended. No drainage was employed. She remained perfectly well for five years and was then suddenly seized with agonizing bladder tenesmus, spasmodic incontinence of urine, an enormous quantity of foul-smelling pus; *x*-ray was negative for stone, and there were no clinical evidences upon examination. Cystostomy was not attempted on account of the violence of pain and inability to hold water in the bladder. Her temperature varied from normal to 101°, pulse was normal to 100. Vaginal examination detected a small mass in the right fornix. There were no menstrual symptoms. On two occasions she had retention of urine and the catheter withdrew on the first occasion a quart of foul-smelling pus containing urine and a week later upon attempting to catheterize her again, a piece of gauze was discovered in the urethra. This was pulled out and proved to be a surgical gauze sponge about two inches wide and ten inches long. The symptoms immediately subsided. In a week's time she was well, cystostomy showing a very small, almost completely healed fistula in the right side of the bladder. The mass could no longer be felt in the pelvis. In a week she left the hospital perfectly well and had remained so.

Malignant Papilloma of the Gall-Bladder.—Dr. T. P. Waring of Savannah reported the case of a woman, forty-two years of age, who had two attacks of puerperal insanity, one of them after an abortion. She had one attack of jaundice after the second attack of puerperal insanity. She had borne four children, three of them without trouble. The family history was negative as to cancer. Present history dated back three years, and started with pain in the right hypochondrium and a feeling of relief on pressure. Three weeks before admission to the hospital she felt a lump in the right side, followed a few days later by pain, which was not severe. There was no fever or jaundice. The only symptom of cholecystitis was a constant feeling of indigestion. A distinct globular mass could be felt in the right hypochondrium, which was a little sensitive to pressure, but otherwise causing no discomfort. At operation a large gall-bladder presented, color rather dark and glistening, walls not very thick. Several masses could be felt in the gall-bladder, and two small lumps along the cystic duct forming part of the tumor mass, apparently in the gall-bladder itself, which proved to be enlarged lymphatic glands. The pathologist reported papilloma, for although the dissection was clean and no other enlarged glands could be felt, the patient developed an obstructive jaundice three months later. This was relieved by establishing a hepaticoduodenal anastomosis over a rubber catheter, making use of the sinus wall to attach to the duodenum, covered and protected by the gastrohepatic and greater omentum. This gave absolute relief for four months. The patient, declining further operation, died two months later from the obstruction.

Congenital Diverticula of the Intestines; Report of Case of a Tumor Growing from the Tip of a Congenital Diverticulum in the Lower Sigmoid Region.—Dr. William T. Black of Memphis said that when the vitelline duct failed to disappear at the end of the seventh week of intrauterine life, a diverticulum was left. These diverticula were present in about two per cent. of the people. They varied from the size of a pea to that of the small intestine, at times being several centimeters in length. They were usually found about 80 to 100 cm. above the ileocecal valve. Through an error in development, they might be found in the large gut. It was Meckel who first described and showed it to be of importance to the surgical world. It was frequently the cause of intestinal obstruction and other abdominal symptoms. He reported the case of a fibromucous peritoneal polyp, weighing 4260 grams, occurring in a female patient, fifty-nine years of age, which was discovered while operating October 4, 1918. This tumor sprang from the peritoneal coat of the tip end of an apparently congenital diverticulum in the lower sigmoid. A preoperative diagnosis was made of a subserous uterine myoma, with cystic degeneration, or an ovarian tumor. The growth probably could be attributed to an embryological condition or fetal rest, or might have followed a diverticulitis, ulceration, or perforation of the diverticulum. The presence of a fecal fistula or mucus appearing at the umbilicus suggested the remains of the omphalomesenteric duct. Tumors or cysts, likewise, suggested a similar condition in this region. The continuance of symptoms of acute or chronic appendicitis, after its removal, suggested a diverticulitis. The patient recovered. Bize, Deve, and Denuce had reported cases of small pancreatic tumors growing from the tip end of a Meckel's diverticulum. Raesfeld described an enterocystoma that developed from a Meckel's diverticulum. Cullen, Cowardine, Rimbach, and others had reported cystic tumors connected to the remains of the omphalomesenteric structure. Rimbach reported a case of cystic tumor the size of a man's head, adherent to the omentum, springing from a congenital diverticulum. In the author's case, the tumor was not connected with any other intra-abdominal structure, except the tip end of a diverticulum. However, a large cyst in the upper portion of the tumor was adherent to the anterior abdominal parietal wall. All diseased diverticula should be removed. Very small or cordlike structures should be excised. Those connected with a large gut, where we had solid feces, should be removed. Where we had a lumen that was large as the small intestine to which it was connected, and was not diseased, it should be left alone for fear of increasing mortality.

Resection of the Cecum and Ascending Colon.—Dr. J. Shelton Horsley of Richmond, Va., discussed the underlying causes of the abandonment of lateral intestinal anastomosis and the adoption of the end-to-end method. Cannon and Murphy had shown that in animals with the end-to-end method there was no stasis of food at the site of operation, whereas in lateral anastomosis peristalsis was abolished where the bowel was united. Dr. Horsley called attention to the triangular space at the mesenteric border of the intestine which was sometimes infected by the operator before it was closed, and to the necessity of cleaning the bowel ends with antiseptics before suturing. He believed that a valve should be made when the small bowel was united to the large. The author described a new operation based on these principles in which the end-to-end method was used and the ileum was projected into the end of the transverse colon and sutured in a manner similar to that used in his method of uniting the small bowel. In addition to this, in order to promote valve formation and increase safety, there was placed a row of interrupted mattress stitches of catgut. To relieve gas accumulation he suggested an enterostomy after the Coffey principle. He reported seven cases which were all the operations of resection of the cecum and

ascending colon that he had done for ten years. All of these patients recovered from the operation satisfactorily. Two of the operations were for intussusception in infants, two for severe intestinal stasis and three for hypertrophic tuberculosis. In one of the cases of tuberculosis there was a resection of several feet of diseased ileum after the cecum and ascending colon had been removed, thus making a double resection in this case.

Practical Considerations in Regard to Permanent Colostomies.—Dr. W. E. Sistrunk of Rochester, Minn., said that at present he was making a colostomy very similar in type to the one which had been described by Mixter. This colostomy was, as a rule, made through a straight incision placed below and about one inch to the left of the umbilicus, although it might be made through a low mid-line incision. An incision of this type possessed distinct advantages. Through it a thorough exploration of the abdominal cavity could be made. If found necessary, a primary resection of the bowel was possible, or the first stage of the three-stage Mikulicz operation could be made; it might be extended in either direction, and if after the exploration it was decided to make a colostomy, this was made through the center or upper end of the incision. The colostomy was made in a loop of the sigmoid flexure, this portion of the bowel being chosen on account of its extreme mobility and the length of its mesentery. After the loop had been lifted out of the abdominal cavity, an incision one and one-half to two inches long was made through its mesentery parallel to the direction of the blood vessels and extending upward nearly to the bowel. A second incision, about one inch long, was then made across the end of the first incision quite near the mesenteric attachment of the bowel. Two strips of gauze were placed in the upper end of the T incision which had been made, and when these were pulled apart a good sized opening was made through the mesentery. The two sides of the entire abdominal wall near the center of the incision were sutured through this opening in the mesentery. The remaining portions of the incision were then closed, a small bit of the bowel being included in two of the sutures to prevent the possibility of herniation of a loop of small intestine. After removing the gauze, a glass rod or rubber tube was placed through the opening in the mesentery between the skin and bowel to serve later as a guide in cutting across the bowel. If necessary for gas distension, a small opening might be made in the bowel any time after twenty-four or forty-eight hours, and after five or six days the bowel was cut across completely with the cautery. As a rule, however, the patients passed gases very readily through the knuckle which had been brought up, and it was unnecessary to disturb it before five or six days. After the loop had been cut across it was found that the two ends of bowels were separated by the entire abdominal wall for a distance of one to two inches. These ends protruded for a distance of from one to one and a half inches above the skin. They might later be cut shorter if thought necessary. The advantages of an operation of this type could be readily seen, and in the author's experience it had obviated some of the difficulties which often occurred following other types of colostomies.

Notes on Two Signs in Chronic Appendicitis.—Dr. Robert T. Morris of New York City stated that two signs belonging to the sympathetic and autonomic nervous system were of prime importance in making a differential diagnosis between chronic appendicitis and other affections of the abdomen and pelvis. These two signs did not belong to acute appendicitis. As a result of the chronic irritation of the appendix, impulses were registered upon the second and third right sympathetic lumbar ganglia known as the fused ganglion in such a way that it became hyperesthetic. Deep pressure upon the abdomen about an inch and a half to the right of the navel and a trifle caudad brought out this hyperesthetic point, which constituted one diagnostic sign of importance in differential diagnosis. The other sign consisted in permanent distension of the ascending colon. It was what he called the cider barrel sign. Percussion upon the normal left side of the abdomen brought out a note suggestive of the cider barrel in October and percussion over the right side of the distended ascending colon brought out a percussion note suggestive of a cider barrel in March. This chronic disturbance of the ascending colon was apparently caused by exhaustion of its sympathetic innervation due to chronic nagging from the irritated appendix.

Surgical Treatment of Goiter.—Dr. Miles F. Porter of Fort Wayne, Ind., summarized as follows: "Usually patients do not consult the surgeon for relief from goiter until the symptoms, either toxic or mechanical, are severe. We cannot hope to achieve the maximum relief that surgery offers in this disease until the patient consults the surgeon before the symptoms become severe. Subtotal thyroidectomy is the operation of choice. Incision should be ample and located with a view to adequate exposure, and the muscles on one or both sides should be divided, when necessary. Incision should follow natural wrinkles and be perpendicular to skin surface. Properly placed sutures will at once coapt divided muscles and fascia and secure against hemorrhage. The hyperactive may usually be distinguished from the inactive or normal portions of the gland because, contrary to the generally accepted idea, these hyperactive portions are lighter in color and softer than the normal. The aim should be to remove the diseased and leave healthy portions of the gland. Portions of the gland to be removed should also be selected with a view of avoiding asymmetry. More than one-fifth of the normal amount of gland structure should not be left behind. Usually it is better to completely divide the isthmus. Preservation of the posterior capsule will protect the parathyroids and recurrent laryngeal nerves. Subcuticular suture, with adhesive plaster is the best method of wound closure. With a few rare exceptions, ether anesthesia is advocated. For the preparation of substandard risks for the major operation injections of boiling water are to be preferred to ligations. Patients with small goiter of the diffuse, hyperplastic variety, may be cured with one or two injections, preferably through a small incision, uncovering the isthmus, so the operator can fill both lobes under guidance of the eye. Goiter symptoms will sometimes disappear promptly upon the removal of foci of infection in tonsils, teeth, etc."

President's Address: The Standardization of Rural Hospitals.—Dr. Isaac S. Stone of Washington, D. C., spoke in favor of bringing the standard of all hospitals, whether large or small, up to that point which would afford the best service to the public and which would require the best medical and surgical training of the staff. Sufficient information had been collected to show the number of poorly equipped hospitals in perhaps all parts of the country in towns and rural districts. Many of these were but a little better than boarding houses, without the essential equipment of house staff or laboratory or, indeed, anything which justified the name of hospital. It was suggested that all hospitals should be inspected by the health officer or commissioner of health, whether they were public or private institutions, and in case they were found up to the standard of requirement they should be duly licensed and required to send in a full report of the treatment of all cases during each year. The writer also favored State aid to rural hospitals when necessary, to provide hospital relief in country or remote outlying districts. Especial attention was given to consideration of rural hospitals as social service centers and for the care of obstetrical patients whose homes were remotely situated or who were unable to obtain competent professional attendance.

Treatment of Tumors of the Upper Jaw with the Cautery.—Dr. Joseph Colt Bloodgood of Baltimore said that the employment of the cautery in the partial or complete removal of malignant tumors was an old method. His own experience during the past five years had demonstrated that we had much to learn as to the details of its application. When we compared the results of operations for the removal of tumors of the upper jaw with the knife alone with the results of the removal of identical tumors with the cautery, we found that we had distinctly decreased the mortality, and when we had accomplished cures it had been with less mutilation. Whether the actual number of cures had been increased could not be demonstrated at the present time. The reduction in mortality was associated with the employment of local anesthesia alone, or in

combination with light chloroform general anesthesia. In many instances it was safer to remove the disease involving the upper jaw in stages. It was remarkable how much could be done under local anesthesia alone. When a general anesthetic was necessary, chloroform, in his experience, seemed to meet the indications best. It did not interfere with the use of the cautery. It was the best anesthetic when operations were performed in the region of the oral cavity. It should never be pushed to complete narcosis. The patient had no memory of pain and, although he was so lightly under the influence of the anesthetic that all reflexes were active, he remained more or less quiet. When chloroform was not pushed to complete narcosis the danger seemed practically eliminated, and the operations could be repeated at intervals of three or four days. In some of his cases there had been as many as fourteen operations. The surgeon should hold himself responsible for the anesthetic and direct its administration. In all of his cases the pulse and blood pressure were recorded every five or ten minutes. The chloroform was rarely administered longer than one hour. When the cautery, instead of the knife, was employed the operation could be discontinued at any moment. The duration of the operation and the number of operations largely depended upon the general condition of the patient and local extent of the neoplasm. When the cautery was employed it was possible to remove the tumor piecemeal and to destroy from tumor tissue into the surrounding healthy tissue without danger of dissemination, while with the knife one must give the tumor tissue a wide margin and remove the entire mass *en bloc* at one operation. In tumors involving the upper jaw the complete excision with the knife, when the disease was extensive, always sacrificed more healthy tissue than when the cautery was employed, and the danger of this single extensive removal with the knife was greater than the removal in stages by the cautery. In the removal in stages with the cautery it was also possible to have a pretty positive microscopic control as an indication that enough had been done. One also learned quickly to distinguish granulation tissue in which there was no tumor tissue from that which still contained tumor tissue by its gross appearance, which could be checked by the removal of a piece for microscopic study with the cautery. The new growth should be attacked with the cautery from two points. One should burn the tissue at the border of the tumor. This not only destroyed the infiltrating area, but excited in the healthy tissue beyond a granulation tissue which of itself was largely protective against secondary invasion, at least during the period of complete removal. The second attack should be upon the new growth itself, if possible, from the center out. These two methods of attack were varied according to the size of the neoplasm and its local growth and the anatomical character of the surrounding uninvolved tissue. He found that he was helped by a thorough knowledge of the character of the local growth and its microscopic appearance based upon a thorough study of similar cases recorded in the Surgical Pathological Laboratory of the Johns Hopkins Hospital. Details of the method of attacking tumors of the upper jaw would be given in the completed paper with illustrations.

Radium Demonstration at the Howard A. Kelly Hospital.—Dr. HOWARD A. KELLY of Baltimore pointed out the continuously expanding domain of radium as a therapeutic agent, emphasizing especially its value in the treatment of new growths, anemias, leucemias, and Hodgkin's disease. Specimens of ores from which radium was obtained were shown, the common salts of radium and radium emanation were described, and the adaptation of the latter to medical usages was pointed out. Dr. Kelly emphasized the fact that radium was not a cure-all, but a valuable aid to surgery and dwelt on the importance of early radical treatment in both domains. In conclusion he pointed out that our present knowledge of the biological and therapeutic effects of radium was rudimentary, and that a vast field for investigation lay just ahead.

Dr. WALTER LANTSBERRY demonstrated the method of separating radium emanation from radium by means of mercury pump and liquid air processes. He then showed some of the physical effects of radium emanation and radioactive deposit, and finally demonstrated some of the completed apparatus used for treatment.

Dr. BURNAM and Dr. KELLY showed sixteen patients who had received radium treatments. These were in the order of presentation:

CASE I.—Miss L. K., aged eleven. Multinodular ovarian carcinoma. Operated on, but tissue only partially removed in February, 1918. Under radium complete disappearance, which had persisted up to the present time.

CASE II.—Miss V. J., aged twenty-three. Posterior mediastinal sarcoma, which had led to paraplegia. Treated between July and December, 1914, with complete recovery. An active healthy working woman with no evidence of paralysis or other disturbance.

CASE III.—Mrs. H. F., aged forty-seven. Cervical Hodgkin's disease, which had disappeared after two treatments in June and July, 1918.

CASE IV.—Mr. J. D., aged thirty-two. Universal Hodgkin's disease. Under treatment for a year. Photographs showing enormous glands. Complete disappearance of glands in neck. Still evidence of change in blood. This case emphasized the importance of rest and feeding.

CASE V.—Mrs. V. F., aged twenty-nine. Medullary carcinoma of right breast and of glands of axilla and neck. Complete disappearance save for very small nodule in breast. Only four months under observation.

CASE VI.—Mrs. E. S., aged fifty-six. Extensive carcinoma of breasts. Complete retrogression of skin nodules and lump in breast without irritation of integument six months after undertaking treatment.

CASE VII.—Mr. I. B., aged fifty. Squamous cell cancer of larynx. Disease limited to larynx. Operative removal by Dr. Samuel Crowe, March 30, 1917, followed by repeated radium exposures. Still entirely well.

CASE VIII.—Mr. H. N. R., aged fifty-five. Extensive basal cell carcinoma of larynx causing obstruction. Tracheotomy and heavy exposure with radium, September 11, 1913. Complete disappearance of growth which had persisted up to the present time. Normal voice.

CASE IX.—Mrs. J. H., aged twenty-two. Round cell sarcoma of tonsil and pharynx. First seen September 6, 1916. Last treated February 4, 1917. After complete disappearance of the growth the tonsils were removed and found normal. No evidence of trouble. Clear throat and neck.

CASE X.—Mr. W. G., aged twenty-four. Unilateral tonsillar hypertrophy or round cell sarcoma. No evidence of trouble since disappearance of growth in August, 1918.

CASES XI, XII, XIII and XIV were instances of localized squamous cell epithelioma of the mouth, well respectively for six weeks, four months, six months, and nine months.

CASES XV and XVI were two instances of skin epithelioma cured respectively for seven and three years.

The Treatment of Hodgkin's Disease.—Dr. CURTIS F. BURNAM of Baltimore stated that during six years he had seen and treated more than one hundred cases of Hodgkin's disease and malignant lymphoma. He wished to emphasize the importance of general *x*-ray, blood, and tissue examination. Blood examination, while quite valuable, was much less reliable than tissue diagnosis. Two glands should be removed in order to secure enough tissue. He advised against extensive operative removals. He employed radium treatment supported by rest in bed, forced feeding, and iron. Where radium was not available he urged the use of the *x*-ray. A critical analysis of cases treated demonstrated that better results were obtained where tissue examination was characteristic of lymphosarcoma than where it showed definite Hodgkin's disease. Also, in Hodgkin's disease the results were better where the polymorphonuclear leucocytosis characteristic of extensive Hodgkin's had not developed. Treatment was much more satisfactory in chronic than in acute cases. In the former, disappearance of gland masses was almost invariably associated with improvement in the general health. No routine treatment applicable to cases indifferently could be prescribed. Each patient must be given individual attention. The best guide to treatment was to be found in the effects of the gland masses, the blood, and the general health

the patient. Gamma radiation at distance of one and a half to five inches from the surface with amounts of radium varying from 500 mg. to several grams, the time of exposure being inversely proportional to the amount of radium employed, was indicated. The radiation should be carried out so that every affected part might receive adequate dosage, and the treatment should be repeated at intervals until all evidence of disease had disappeared. The results obtained were highly encouraging. Where lymphosarcoma was diagnosed, two cases had been well for more than five years, one with extensive neck, and one with abdominal, involvement. Four cases had been apparently well for over three years; one with pharyngeal and neck involvement; one with mediastinal, one with tonsil, neck, and groin, and one with neck and axillary involvement. In the cases of Dorothy Reed's Hodgkin's disease, one patient with mediastinal and neck involvement had been well for four years, and two cases for more than three years. One of these had neck, axilla, groin, and iliac, the other groin, axillary, neck, and mediastinal involvement. No analysis was given of those cases under observation less than two years.

Mustard Gas Burns.—Dr. WILLIAM P. CARR of Washington, D. C., reported a number of cases of burning with mustard gas. He spoke of the remarkable difference between these burns and ordinary burns or scalds. The remarkable features were, he said, as follows: (1) A long period between exposure and the appearance of any symptoms, which varied in his cases from sixteen to thirty-six hours. No disagreeable sensation was felt on exposure and patients were sometimes not aware that they had come in contact with the gas until a day or two later. (2) The destructive action of the gas absorbed into the tissues continued for days and in one case continued for two and a half months. (3) The symptoms began with stinging and itching sensations, much brown pigmentation of the skin and a few hours later vesicles appeared which soon coalesced into large blebs filled with coagulated lymph stained a deep yellow with broken down hemoglobin. These blebs always destroyed the whole thickness of the skin and might extend deeper. They were solid and looked and felt much like lipomata after they had been removed. Fluid from these blebs was very irritating and might cause burns on the sound skin. Some of these blebs were two or three inches in diameter and elevated an inch above the surface. (4) During the active stage the burns were extremely sensitive. (5) Some persons were practically immune to the gas and the degree of susceptibility varied greatly in different inviduals. (6) Healing was fairly rapid except under the blebs, where continued destruction after their separation or removal might continue for a long time after other parts of the wound had healed. (7) The most satisfactory treatment he found was removal of the blebs with curved scissors, thorough cleansing with sterile water, thorough drying with a warm air blower, and the application of ambrine or paraffin with a spray. Cauterizing sloughs with silver nitrate was followed by severe reaction and did harm. (8) Very little scar followed under ambrine or paraffin treatment.

Some Notes from the Examination of Five Thousand Selected Service Registrants.—Dr. ALEXIUS MCGLANNAN of Baltimore reported some points from the examination of five thousand men by Drs. Requardt, Hutchins, and himself, surgeons to Medical Advisory Board No. 2, Baltimore. There were 3500 whites and 1500 negroes examined. Inguinal hernia was found in 294 whites and 78 colored men; femoral hernia only 7 times; umbilical hernia in 5 whites and 20 colored. Of 255 varicoceles only 2 occurred in black men. Undescended testicle was found in 26 cases. Among other congenital defects, there were 2 cases of absence of the pectoralis major muscle.

Anesthesia.—Dr. HENRY O. MARCY of Boston said that the history of surgery gave unmistakable evidence that from the very early period of Egyptian civilization, through the many centuries, the medical profession made earnest effort to control pain and lessen suffering because of surgical need. The remedies used were considerable in number. First, and most important even to the present time, was alcohol and its derivatives, of which sulphuric ether was the most important. The knowledge of the effect of the poppy was certainly of long ago, and its socalled juices were used in various products. The ancient Peruvians early ascertained the value of the cocoa plant; its leaves were in general use among all classes, from the laborers to the Incas, who by royal edict consecrated it to the gods. Inhalation of various volatile products was in more or less common use and the problem of the control of pain was never forgotten. It was a singular coincidence that men unknown to each other, of limited knowledge and training, should independently and almost simultaneously have demonstrated the great value of sulphuric ether. America was justly credited with the discovery and introduction of this priceless boon. On the other hand, Sir James Simpson was one of the leading surgeons of Europe in training and knowledge. To him was rightly due the discovery of chloroform as an anesthetic. Dr. Marcy emphasized the just value of anesthetics, not alone in the relief of the suffering incident to surgical intervention but especially in the revolutionary progress of the surgical art, broadening the field of surgery into that of true science. To the present generation the great surgical advance was accredited; the discoveries of Pasteur, Lister and his pupils thus having completed the Esculapian temple of the present. The building of the fathers in the early centuries was ever to be held in reverence by the worshipers of the present day. The future was yet full of promise and the field of medicine at the present could enroll its victories, not less brilliant than those of surgery. In both, however, as never before, science pointed to still greater achievements.

Reconstruction of the Uterus.—Dr. CHARLES R. ROBINS of Richmond, Va., approached the subject from two points of view: first, the obvious advantages of exploring the cavity of the uterus through a direct incision. In this way many cases could be relieved without resorting to the radical measure of removing the uterus. From the other viewpoint the consideration was the removal of the pathological portion of the uterus and its reconstruction from the portions left. This procedure was facilitated by the anatomy of the organ. The blood supply and the tubes entering from the sides made it possible to remove as much of the intervening portion as might be necessary. The only thing necessary to leave was a continuous cavity from the tubes to the external os. This operation could most frequently be practised in the treatment of fibroids. It was not intended that it should be generally used because the cases in which it was indicated or possible were comparatively few. However, in young unmarried women and in married women who had not borne children we would be justified often in whatever risk we might entail of unsatisfactory results or later development of fibroids. Two cases were reported. One in which a young unmarried woman was relieved of a profuse menorrhagia due to a fibroid infringing on the endometrium, and the other in which fibroid and fibrosis of the uterus were removed by extensive resection extending to the internal os and the reconstruction of the uterus by suturing the lateral portions together. In this case the patient subsequently married and became pregnant three times without pathology, except that she aborted in the first two pregnancies. Her last pregnancy, however, resulted in a robust, living child.

Gynecological Pelvic Drainage; Its Indications, Methods, and Materials.—Dr. J. WESLEY BOVEE of Washington, D. C., contrasted the attitude of the medical profession toward drainage forty years ago and the present. He claimed there was still much need for the use of drainage material in pelvic surgery, at the same time deprecating the suprapubic use of it and pronouncing in favor of the vaginal route for its use. He mentioned the various materials in use, but especially recommended for the purpose paraffinstearin gauze as prepared by the formula of Dr. Hart E. Fisher, chief surgeon of the Chicago Elevated Railroads (*Jour. A. M. A.*, 1916, LXVI, 939), which he had used since March, 1916. The chief advantages claimed for it were (1) its non-adhesion to the tissues and consequent easy and painless removal, and (2) its permitting endothelialization of denuded areas of pelvic peritoneum without the formation of lasting adhesions.

Visceroptosis.—Dr. CHARLES L. BONIFIELD of Cincinnati, Ohio, said that some of his cases of ileosigmoidos-

tomy had been under his observation for five years and were still doing well. In none had he found it necessary to remove the colon, although the colon was removed in one case by a surgeon while he was out of the city. He had always felt that his youthful enthusiasm led him to do an unnecessary operation. Some of them had had slight trouble with feces getting into the colon above the anastomosis, but to the best of his knowledge in none of them had it been serious, and as time went on it became less and less frequent. Reed of Cincinnati for a time removed the colon in all of his cases of ileosigmoidostomy, but he found the operation attended with a high mortality rate, and in later operations he left the colon, but severed it just above the anastomosis and brought that end out to the skin on the right side of the abdomen and the end of the ileum out on the left side, so he could wash through and through the unused portion of the bowel. His results with this procedure were very satisfactory and he never found it necessary to remove the colon afterward. The same beneficial results could be obtained by doing an ordinary appendicostomy or cecostomy without severing the colon. The mucus and any feces that accumulated in the transverse colon could be washed into the lower bowel, but his experience, although limited, would lead him not to do even this until symptoms indicating it arose. He performed cecosigmoidoscopy on three patients, but his results were not as satisfactory as he had always obtained from ileosigmoidostomy. A large part of the fecal current continued to flow through the old channel and to produce the old symptoms. The result of his study and experience with this condition would lead him to believe that many cases required no surgical treatment; that others required operative treatment only for the pelvic condition; others would require fixation of the kidney as well, and for the type where colonic stasis was most severe ileosigmoidostomy was the best procedure yet devised, and that the colon should be removed at a second operation and only when symptoms made it necessary.

Treatment of the Undescended or Maldescended Testis with Particular Reference to End Results.—Dr. WILLIAM B. COLEY of New York City read a paper with this title in which he reported 415 cases and drew the following conclusions: "(1) In most cases of undescended or maldescended testis the etiology points to a congenital origin, often influenced by the element of heredity and frequently associated—particularly in the double variety—with other developmental defects. (2) As to the question of the functional value of the undescended testis, while it cannot be definitely answered in an individual case, it is probable that in a considerable number of cases, at least 10 per cent., the testis retains the power of spermatogenesis. (3) The testis should rarely be sacrificed, especially in children, for two reasons: (*a*) Because of its possible functional value; (*b*) because of the interstitial cells which are present in all cases and which have an important influence in the development of the male characteristics of the child. (4) The tendency to malignant disease is relatively considerably greater in the undescended than in the normal testis. (5) Operation should be advocated in children who have reached the age of eight or ten years, for the following reasons: (*a*) For the radical cure of the hernia with which the undescended testis is practically always associated and which often cannot be controlled with a truss without causing pain and irritation to the testis; (*b*) by bringing the testis down into the scrotum at this period there is a possibility of causing further and more normal development of the testis. (6) Operation in adults over the age of fourteen should be even more strongly urged, for the following reasons: (*a*) In order to cure the accompanying hernia; (*b*) in order to place the testis in a position in which it is much less liable to trauma, thereby lessening the chances of malignant degeneration; (*c*) for the mental and moral effect upon the patient."

Notes on the Treatment of War Wounds in the Hospitals of the A. E. F.—Colonel CHARLES H. PECK, M. C., U. S. Army, formerly Senior Consultant, General Surgery, A. E. F., stated that the scientific treatment of war wounds was developed greatly during the second and third years of the war in the French, British, and Belgian services. It passed from the stage in which all wounds suppurated profusely, to the discovery of the Carrel-Dakin method of chemical sterilization, and later to the method of early "debridement" healing by first intention in a large percentage of cases. Successful early debridement depended upon well equipped operating hospitals near the fighting line; upon conditions of combat and transport which permitted of evacuation of the wounded from the field to the operating hospital in less than 15 hours; and upon an adequate number of skilled operating teams to care for all wounded promptly in time of battle. These conditions had been met in the French and British Services by the evacuation hospital and the casualty clearing station, established 8 to 12 miles behind the lines, and by large numbers of mobile operating teams which were moved as needed to meet the changing demands of battle at different points. The American Service was developed on similar lines, but soon had to meet the changed condition of open warfare as contrasted with the fixed line of trench fighting, which had existed for more than two years. In open warfare the frequent delays in evacuating wounded from the field; the difficulty of providing for early operation near the front for all cases needing it; the necessity of using small mobile hospitals, and improvised operating units in field hospitals, instead of well organized evacuation hospitals, had interfered seriously with the ideal treatment of war wounds. In spite of these difficulties and new problems, the Medical Department of the A. E. F. had met the situation in a masterly way; had provided adequate hospitalization and skilled surgeons for the care of the wounded, and had performed this gigantic task for an army of two million men with a minimum amount of confusion and delay. The excellent morale and the good physical condition of returning overseas wounded was evidence of the efficiency of the service.

The Limitations of Cesarean Section.—Dr. E. GUSTAV ZINKE of Cincinnati, after a brief reference to the history of cesarean section, the evolution and completion of the doctrine of narrow pelvis, the introduction of the compromise operations (namely, induction of premature labor, the high forceps, version of the child, and embryotomy in any of its forms), and a general consideration of the positive and relative indications for cesarean section, as well as the reasons for the present popularity of the operation, summarized as follows: "(1) Abdominal cesarean section is positively indicated, as in the past, in all cases in which the child cannot be delivered by any means, dead or alive, through the parturient canal. (2) The operation is not only justifiable, but almost imperative, and should be selected as the best mode of delivery in all cases of deformed, narrow, and contracted pelves in which the diameters are so reduced in size as to forbid the test of labor, the use of the high forceps, or version of the child upon the feet. (3) Abdominal hysterotomy will furnish the best results for both mother and child in all of those cases of placenta previa in which the hemorrhage is either profuse or moderate and protracted, and beyond control. When an elongated or unobliterated cervix or rigid os complicate placenta previa, cesarean section is all the more imperative. Fortunately, in the majority of these cases, the hemorrhage may be effectually arrested; elongated cervices are quite rare; and an unobliterated cervix, or rigid os, usually yield to well applied tamponade, or the careful and skillful use of the rubber bag. (4) Cesarean section may be chosen as a just procedure in cases of sudden and profound eclampsia, or severe toxemia in a primigravida when associated with an elongated or unobliterated cervix, acute suppression of the urine, general edema, and cyanosis. In the milder cases of this disease, when the life of the child is considered equally as important as, or more important than, the life of the mother, the operation finds a justification. This fact, more than anything else, renders cesarean section almost entirely unnecessary in the treatment of eclampsia. (5) As to the advisability of abdominal hysterotomy in cases of asthenia, no matter what the cause, the justification of the operation rests upon the mature and accurate judgment of an able, conscientious and experienced attendant. That, occasionally, both lives may be saved by the performing of this operation in these circumstances may be granted; but that the operation will be but rarely indicated for this condition, also admits of no doubt. (6) In the past, cesarean section was not resorted to

often enough; at the present time, it is performed too frequently. In order to guard against an abuse, it may be well to establish the custom that the cesarean operation should never be performed without the consent of an experienced consultant of recognized standing and an authority on obstetrics. (7) Cesarean operation should never be regarded lightly because it is easy of performance; on the contrary, it should always be considered a formidable procedure, one which may be followed by serious consequences; and it should not be forgotten that, even under the most favorable circumstances, the operation invariably involves extensive exposure of the abdominal and uterine cavities; it means an abdominal and uterine cicatrix and, nearly always, more or less extensive adhesion between the uterus, abdominal wall, omentum, and intestines. In addition to this, it is well to remember that the danger from a septic infection cannot be, and never will be, entirely eliminated. (8) The question as to whether an existing septic infection is a contraindication has been discussed repeatedly and extensively. Judging from the favorable results reported by men who have performed cesarean section when the patient showed symptoms of infection, one is led to believe that the cases in which recovery did take place were not really of the type classified as true septic infection, but rather that they were cases of mild sapremia. A strictly septic infection is always systemic and almost invariably fatal; a sapremia is, usually, local in character, and even if some of the saprophytes do find their way into the circulation the police force within the organism, as a rule, promptly disposes of them, and the patient recovers notwithstanding the cesarean section."

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 19, 1918.

DR. EDMUND P. SHELBY IN THE CHAIR.

Pulmonary Abscess Following Aspiration of Sea Water. Dr. JESSE G. M. BULLOWA presented this paper in which he reported four cases showing that the inspiration of sea water was apparently a frequent cause of pulmonary infection which might lead to abscess formation. In three of the cases recovery was spontaneous, while the fourth, a more severe type, was treated bronchoscopically. In all of these cases there was a history of sea bathing and of having swallowed sea water just previous to the appearance of symptoms. The outstanding symptoms in these cases were cough, initial high temperature, purulent or mucopurulent sputum, flatness, bronchial voice and breath sounds, and increased fremitus, referred to one side of the chest. There was an absence of tubercle bacilli in each instance. The first three cases recovered under rest in bed and sedatives, in the course of from three to six weeks. The fourth case was more severe, giving a history covering over six months, and was treated bronchoscopically. About seven weeks ago Dr. Lynah bronchoscoped this patient and aspirated pus from the posterior branch bronchi of the left lower lobe. The pus was cultured and developed a *Staphylococcus albus*, a yeast fungus, and two types of streptobacilli. Following this procedure the sputum lost its odor, the boy improved rapidly and gained weight. This was probably due to improved drainage resulting from the dilatation. About three weeks ago the odor returned and the boy was again admitted to the Polyclinic Hospital, where he was bronchoscoped a second time by Dr. Lynah and the cavity in the right lower lobe washed out with tincture of iodine. There was a very slight though definite improvement from this procedure. About a week later he was again bronchoscoped and washed with iodine, the bronchoscope being passed into the affected bronchus, a distance of 32 cm. from the teeth, and 10 per cent. silver nitrate was applied. There was a characteristic ulcerative turnescence in the bronchus leading from the cavity. How salt water caused lesions in the lung was an interesting problem. One could not say whether the fluid carried down an extra charge of bacteria from the mouth with which the tissues became saturated, producing the phlegmon in the lung, or whether the salt water acted as a foreign body and by some chemical action inhibited the cilia which should expel it, or whether the salt water had a peculiarly irritating action on the pulmonary tissue. It was also possible that there was an edema of the pulmonary tissue sufficiently intense to cause a retention of the normal secretion which decomposed and acted as a foreign body. The diagnosis depended upon the probable inspiration of sea water in the so-called "colds" which were subsequent to immersion and on the presence of unilocular physical signs. Confirmatory evidence obtained by *x*-ray examination and the characteristic appearance of an ulceration of the bronchus leading from an affected area were further aids in the diagnosis. The absence of tubercle bacilli was valuable confirmatory evidence though not conclusive, as patients with tuberculosis might acquire this condition. It seemed probable that the proper understanding of the etiological factors and the employment of modern methods and study would result in the improved care of these sufferers, and that a widespread recognition of the mechanism of this type of pulmonary abscess as a foreign body irritation and the prompt employment of bronchial aspiration would prevent the occurrence of some of these cases. This fact should be brought home to all surgeons who were likely to see cases of submersion, as would doubtless be the lot of those who went overseas.

Dr. JACOB PILLER asked Dr. Bullowa if he considered the first three of these cases pulmonary abscesses.

Dr. BULLOWA said "no," he thought they were phlegmons.

Dr. PILLER recalled that it had been his good fortune, in 1915, to observe six or eight cases of pulmonary abscess following tonsillectomy, and he had also followed several cases in private practice. In none of those cases was there observed anything more than a very brief temporary spontaneous cure. In one case, after hygienic treatment, the radiographic shadow cleared up but upon the man's returning to work the symptoms recurred, and he had since become steadily worse. None of the others did clear up and all had been bronchoscoped and were without question true pulmonary abscesses. The *x*-ray showed in the majority of the cases abscess formation around the root of the lung. Two were at the base, and the shadows were all much heavier than those shown by Dr. Bullowa, and were characterized not so much by their severity of symptoms as by their long continuance.

Dr. HENRY LOWNDES LYNAH said that he had been seeing one of Dr. Bullowa's cases. In his personal experience he had seen a lung abscess follow a tonsillectomy, but had never seen one follow the inspiration of sea water until he saw this case of Dr. Bullowa's. However, he was not surprised that a lung abscess should follow the inspiration of sea water, because the colon bacilli was very generally found in the sea water about New York and might be the cause of infection. Dr. Yankhauer had treated many lung abscesses by bronchoscopy. In bronchoscoping these cases he had never been able to see a definite abscess cavity; the only thing he had been able to see was pus coming from a small bronchus.

Dr. SHELBY congratulated Dr. Bullowa on the results obtained in these cases. He said he had seen many cases of lung abscess, but he had never seen a case recover without operation. He believed we had come to consider that these were surgical cases, only to be cured by surgery, and the idea of aspirating them through a bronchoscope struck him as a most advantageous and excellent procedure, and he hoped that it would have a large field of application.

Dr. BULLOWA, in closing, emphasized the fact that the recognition of these cases of pulmonary infection due to the inspiration of sea water and the possibility of their resulting in abscess was important. These cases were foreign body infections of a definite type. Dr. Evans had seen two such cases. Frenkel and Stahlin, as well as Godlee and Stewart, reported no cases of this kind in their works on diseases of the lungs.

The Work of the Cardiovascular Board at Camp Upton.—Captain EDWARD J. RILEY, M.R.C., read this paper in which he stated that the work of the board of cardiovascular examiners included the following: (1) The preliminary sorting of those who presented

unmistakable signs of heart disease, such as well defined mitral stenosis, aortic regurgitation or aneurysm, cases which presented an appreciable displacement of the apex beat to the left, and cases with a severe and persistent form of cardiac irregularity, and also those presenting signs of exophthalmic goiter. (2) The subsequent reexamination of soldiers who suffered from the strain of training. (3) The study at the hospital of such cases as were indefinite and needed observation. Recruits were examined within twenty-four hours of their arrival. During the time a large increment of men was arriving it had been the custom to examine about 1,800 a day. The general examination was made by six examining teams, working in two shifts. The power of rejection was not given to these men, so a case in which there was any question of the fitness of the recruit was referred to a special board of examiners. It was estimated that in order to complete the examination of 1,800 men a day, 200 men per hour must be examined. Therefore, three teams working, each man must examine 60 odd men an hour; in order to complete the examination of 60 men an hour he could allow himself approximately one minute for each examination. The general examining room was very noisy and one could imagine that a great many organic valvular diseases might easily slip by, but to show how careful the examiners were Dr. Riley read the figures relating to three of the increments of men that arrived at the camp in daily quotas of 1,800 or 2,200 men a day. Of one increment numbering 10,843 men, 339 were referred for special cardiovascular examination. Of these 279 were accepted and 60 were rejected. Of a second increment numbering 1,150 men, 66 were sent for special cardiovascular examination, and of these 55 were accepted and 11 rejected. Of a third increment numbering 8,365 men, 320 were sent for special cardiovascular examination, of which 302 were accepted and 18 rejected. Taking these three groups together, there were 20,358 men, of whom 89 were rejected on primary examination for cardiovascular disease which would incapacitate them for full military duty, 625 were accepted, and 71 were rejected after a second examination for organic cardiovascular disease. According to instructions from the Surgeon General's Office, medical examiners might accept for general military service recruits showing: (1) Loud systolic murmurs, audible at the apex and in the left back, if unassociated with any definite enlargement of the heart, with snapping first sound, or accentuation of the pulmonic second sound, in whom the response to exercise was normal, but the actual physical signs found present would be entered on the record. (2) Displacement of the apex downward to the sixth interspace within the nipple line, without evidence of hytertension or aortic disease, could be accepted with notation. (3) Displacement of the apex toward the left beyond nipple and not associated with signs of mitral disease, with normal response to exercise. (4) Basal systolic murmurs not associated with cardiac hypertrophy or palpable thrill might be accepted with notations. (5) Cases of tachycardia not associated with hyperthyroidism or tuberculosis, with normal response to exercise, might be taken with annotations and request for reexamination. (6) Mild cases of arrhythmia were accepted. Practical experience had shown that the presence or absence of systolic murmur was of no value in estimating the soldier's capacity for work, and this practical conclusion held irrespective of the character of conduction or point of maximal audibility of the murmur in question. When cases were referred to the cardiovascular board for primary examination a complete record was taken of the name, age, occupation, and the abnormal signs for which the case was referred, as well as the previous history of the man. After the general physical and cardiac examination, the recruit was subjected to exercise, having him hop on one foot 100 times; if he could not complete the 100 hops with one foot he did so with the opposite one. His heart was then auscultated while he was standing and then in the supine position. The heart rate after exercise and the time required for it to return to normal limits was recorded. Under caption D the findings of the special examiners were recorded. Under caption C the recommendation of the special examiner was noted. The recommendations thus far were only to accept or reject, there being no waiver for special duty. After the examination of an increment was completed a duplicate report was forwarded to the Surgeon General's Office. Many of the cases presenting themselves for examination at the present time were very puzzling, especially those sent with the diagnosis of tachycardia. In a few of these cases the condition quieted down and the recruits were accepted for duty; some few were persistent and tuberculosis was suspected and the men were referred for a special lung examination. A great many presented the symptoms of hyperthyroidism, this complex being observed in 13 of 60 cases rejected in one increment. The subsequent examination of the soldier who suffered from distress upon exertion was made once a week at the recruiting barracks in the camp, and the regimental surgeons brought these cases to the special board of examiners. It could readily be seen how a soldier would grasp the statement made by a physician that his heart was affected, especially if he were not anxious to serve. To tell a soldier directly or indirectly was to prejudice his return to duty. So the use of the cardiac terms for describing the cause for the symptoms was discouraged and the term "effort syndrome," so wisely chosen by Dr. Thomas Lewis of the Hampstead Military Hospital, England, had been adopted. The reexamination was conducted in exactly the same way as the special primary examination. For the most part the chief complaint was equally divided between breathlessness on exertion and pain over the precordium; many complained of palpitation, faintness, dizziness, sweating, and exhaustion. Inquiry showed that these symptoms were most likely to occur after exercise and that double-quick time for the most part was the cause. During the survey for tuberculosis a division was practically combed of all cases of organic heart disease. Monthly reports were sent to the Surgeon General's Office of the cases examined and reexamined and a description of each case was included.

Dr. Selian Neuhof said that he wished to speak on the adventitious heart sounds heard at the apex. Last summer he had occasion at the local examining boards to make examinations; in some cases he found a thrill-like impact with the first sound at the apex. These cases had been to a number of doctors and all sorts of diagnoses had been made. Upon auscultation one at first got the impression of a real presystolic mitral murmur. The thrill in question was, however, systolic in time and could be quieted by having the patient hold his breath at the end of inspiration. Under such procedure the murmur would disappear and the heart sounds become normal. In a few cases sounds were noticed that were due to localized pleuropericarditis at the apex, probably from an old pneumonia. Nothing was said of these sounds in textbooks, but having one's attention called to it might be of assistance in distinguishing organic lesions from adventitious sounds.

Dr. Bullowa related an interesting experience that he had had on one of the local boards and as a visitor to its advisory board. He observed that some men who had rapid hearts at the local boards and who were sent for examination to the advisory board had lost their abnormality when examined at the advisory board. He had also observed a few cases in which there were adventitious sounds that disappeared under vagus pressure. There were a large number of overweight men who on examination were found to have hypertension. These were young men and sometimes the blood pressure reached as much as 280 mm. They seemed to be suffering from a pituitary disturbance which was associated with a genital hypoplasia.

Dr. Shelby asked whether in these cases kept under observation with physical training they had any of anemia, and whether when they found these men who came from sedentary occupations and did not pass the tests they had made any observations with reference to the hemoglobin. Some of these men who were under par and came from sedentary occupations had a hemoglobin percentage of from 50 to 75, and that was a factor that might be taken into consideration.

The Cardiovascular Ward at Camp Upton.—Dr. Ami Edgar, Captain, M. R. C., presented this contribution, in which he stated that there appeared before the Cardiovascular Board a number of cases of uncertain and indefinite character which required a period of observation in order to classify and deal with them properly

and fairly. Among these were the organic cardiac conditions already described by Dr. Riley, together with a fair proportion of conscious exaggerators and true malingerers. The object of the observation hospital was for the immediate removal from duty of such cases as might suffer more or less permanent harm, and for the invaliding of men out of the service who had permanent disease unfitting them for further duty, and for the treatment of the remainder of these doubtful and uncertain cases to the end that they might be returned to duty at the earliest possible moment. They maintained at the Camp Upton Hospital an observation ward and two convalescent wards where the retraining exercises were carried on. All cases unfit for further service were eliminated as rapidly as possible, the procedure being practically a repetition of the work of the Cardiovascular Board in Camp. A considerable number of cases found in the cardiovascular ward were from time to time collected from the various wards, having been sent to the hospital for other than cardiac conditions. These men were, as a rule entirely ignorant of any cardiac disorder, which was usually, of a kind not easy to diagnose offhand, and having allowed them to pass at a single examination was quite excusable. This left them with patients who displayed the symptoms and signs of the "effort syndrome," complicated or not by the presence of systolic murmurs. They did not make any further attempt to diagnose organic disease of valves or muscle at this time for the question now became one of prognosis rather than of diagnosis. The frequency with which these symptoms developed during convalescence from febrile affections demanded for those cases also a very gradual transition from hospital to duty, and accordingly they were added to the lot. All these cases were placed on graduated exercises, directed by a sergeant and two assistants. The exercises were adapted from the manual of drill and were in a measure familiar to the men. They were taken daily at stated times and the patient advanced to a higher grade and more difficult exercises according to his response to to-day's exercises. Each patient was examined after taking a new exercise and more often if it was considered necessary. Observation was made and noted of heart rate, respiratory rate, and objective signs of distress were carefully compared with subjective symptoms. The appearance of the man coming from drill, his expression, color, breathing, and heart rate, were invaluable objective clues to his tolerance of exercise. The patients gradually classified themselves according to the highest grade of exercise that they could bear without distress, and in estimating fitness for duty these were far the most important guides, for a man's observed capacity to accomplish work of a given order was the only dependable test of such capacity. Observation of the physical signs while the patient was at rest were absolutely unreliable for estimating capacity for work. A man with stationary aortic disease was frequently capable of far greater and more prolonged strain than was a man with the severe "effort syndrome" symptoms who had no murmurs. Neither could the patient's statements be relied upon to any extent. The very properly called "effort syndrome" group of symptoms invariably presented some very interesting and frequently puzzling points. Some of these cases were with great difficulty separated from the organic. The chief symptoms which these patients complained of were breathlessness, an almost constant feature and almost without exception all out of proportion to subjective symptoms; exhaustion, provoked to a degree far in excess of that due to fatigue in healthy men; pain, which was present in 70 to 80 per cent. of the cases and varied from precordial uneasiness to severe, sharp, stabbing pains, though most frequently a dull ache of indefinite character was present; palpitation, commonly the expression of a vigorous heart action which was present or severe chiefly during exercise or when under emotion, though it might be maintained under all conditions; fainting, sometimes genuine, which might occur under almost any condition, as standing, walking, marching, or after inoculation; giddiness, which was present in more than 70 per cent. of the cases; sweating, also of very frequent occurrence. In the effort syndrome the heart rate averaged 85 to 90 or even 100 or more, and in most cases was an exaggerated response to normal stimuli. Systolic murmurs were dealt with according to instructions from the Surgeon General's office. The essential factor in dealing with the irritable hearts of soldiers was to draw their attention away from the heart. Such terms as "cardiac strain" and "irritable heart" should not be used in the presence of the soldiers if they could be avoided. The expression "effort syndrome" was noncommital from the pathological standpoint and adequately described the clinical picture, in that it expressed the fact that the chief symptoms were unmasked or aggravated by exertion. As the retraining of these men progressed they were able to make still further eliminations, as, for instance, if a man showing breathlessness on exertion had been tested objectively and this was found to be persistently severe, or those in whom the heart rate was persistently above 120, even in the recumbent position, or those in whom a simple exercise test produced marked objective signs of distress, namely an anxious expression, a respiratory rate of 35 or more, which persisted while the patient was recumbent, and a pulse rate which fell to within five beats of the pre-exercise level on lying down two minutes. It was at this stage of the game that the malingerer and conscious exaggerator were met up with. Dr. Edgar said they observed the entire training period of the 77th Division, which was almost entirely a metropolitan division, many of the men coming from sedentary occupations. While these men had been carefully and intelligently trained, it might be wiser in conscripting men from sedentary life to give them a more graduated course of training, for the sudden transition was without doubt the cause of considerable disability in a certain fairly large proportion of these men in the early weeks of camp life. The hospital retraining was a splendid one.

Dr. Selian Neuhof asked whether they were using any drugs of the bromide group in the cases of tachycardia, or in those cases having fairly well-marked precordial pain.

Dr. Louis Faugeres Bishop expressed the opinion that the work carried on by the cardiovascular boards in the Army was most extraordinary in regard to the rapid manner in which the army men had come up to the standard of those who had been working on cardiovascular diseases for many years. Of course every man who specialized in diseases of the heart made one rediscovery and that was that exercise was the best remedy for heart disease. Formerly it was thought that rest was the best treatment for a patient with cardiovascular disease, so the general practitioner always put the patient to bed and the specialist in cardiovascular diseases came along and got those people up. The army men had in a short time come to hold the same views as the heart men had reached through long observation. It was also extraordinary the way in which the army men had put these views into practice in such a short time.

Dr. Shelby said that those of them who had been examining the recruits were very anxious to hear the final decision in reference to cases that had slight cardiac symptoms. They were glad to know that they could take cases not entirely normal and by properly training make them fit. It was gratifying to know that in cases in which it was difficult to make the decision as to whether the men should be accepted or rejected that by a series of exercises they could find out whether the men were fitted for service or not.

Dr. Edgar, in closing, said they had had some very few cases of anemia. They had had some men who were very much under par in every way, and one could not say definitely that there was any one thing that was the cause of their condition, and they had had a few cases of anemia. As to the use of drugs, they were not using drugs, for a case that required digitalis was unfit for military service. Exercise, good food, and good hygiene were the measures they were employing in the treatment of these cases. They did not allow these men to go to bed. The bromides they had used in the cases of exophthalmic goiter, but simply to tone them up.

The Relation of Bronchoscopy and Laryngoscopy to the Field of General Medicine.—Dr. Henry L. Lynah made this presentation, which consisted of a lantern slide demonstration. He said that he felt a little out of place in attempting to teach the internist about

bronchoscopy since those interested in general medicine did not seem to be much interested in bronchoscopy. Dr. Lynah showed slides illustrating the position in which the patient was placed for bronchoscopy and called attention to a number of technical points in the procedure. He stated that the measurements of the tracheobronchial tree varied in circumference from 4 cm. at the age of two years to 17 cm. at the age of 23 years. He emphasized the importance of having the *x*-ray taken in the lateral position in trying to locate a foreign body. Among those wearing tubes it occasionally happened that a tube disappeared and it was thought that the tube had been coughed up and lost; later the tube would be found to have been pushed down into the lung. This would not be discovered until an *x*-ray was taken. The tubes were so constructed that they could not fall into the lung, but it was possible to push a tube down if a forcible effort was made to remove it. A case of peribronchial abscess for which no cause could be assigned was found on bronchoscopical examination to have been caused by the presence of a safety pin in the bronchus; this served to show the value of a bronchoscopical examination. In cases such as Dr. Bullowa had reported the bronchi showed, when examined bronchoscopically, a soft edematous tumescence which tended to occlude and interfere with drainage, and the ulcerated area that was caused by the passage of the irritating fluid from the abscess cavity. Dr. Lynah said he did not think the value of bronchoscopy would be realized by the general practitioner until he learned that it was possible to go on with the bronchoscope and tell whether a child had bronchial diphtheria or not. Dr. Gover had recently done some very interesting work showing that this could be done. Before it was demonstrated that one could recognize the presence of bronchial diphtheria by means of the bronchoscope and could remove the cast that frequently formed in the bronchi, these cases often went unrecognized. It was well known that even when the presence of a bronchial cast was discovered and the cast removed it was likely to recur. Now, after removing the cast, the bronchus was swabbed out with antitoxin and a tube left in, and it had been found that the cast would not reform around the tube. In these cases of bronchial diphtheria in which a cast obstructed the passage to the lungs the pathological changes were likely to be very great; in one instance almost complete necrosis of the lung had taken place. This was in a man over 80 years of age who was supposed to be suffering from pulmonary edema. The bronchoscope revealed the presence of casts in the bronchi. The man died as the result of drowning in his own secretions. Cases of tracheobronchial diphtheria often looked much like bronchitis, but they might be distinguished by the absence of respiratory murmur and the increased resonance, together with the aid of a bronchoscopical examination. Bronchoscopy could be performed in twenty minutes in a child and in thirty minutes in an adult. There was no danger incident to the procedure when it lasted only this short time. Dr. Lynah also showed illustrations of pouched diverticula in the bronchi and said that although efforts had been made to clean these diverticula out the patients all died.

Dr. LEWALD recalled that Dr. Jackson had said that nobody need go to Pittsburgh to be bronchoscoped since Dr. Lynah had taken up this work. He said that the question of abscess of the lungs had interested him very much and that he had been able to follow many of these cases. Some of the cases did not seem to have pus pockets but seemed more like cases of bronchiectasis with some infiltration of the bronchi. The pus seemed to come from the bronchi. A true abscess was formerly regarded as an indication for surgical interference, but our views were undergoing something of a change since we had learned what could be done by bronchoscoping these cases and washing out the bronchi. Dr. LeWald said they had a case at St. Luke's Hospital in which Dr. Green washed out the bronchus with iodine, and after that was done there was a change in the character of the secretion, and the odor was diminished. He felt sure that when the advantages of bronchoscopy were better understood more of these cases would be treated as medical rather than surgical cases. Dr. LeWald related an instance in which a patient was operated on for empyema as a result of which there was a persistent sinus and later it was found that a tack was the cause of the trouble. This led him to insist that cases of supposed empyema should be radiographed before being subjected to operation. There was always the possibility of the presence of a foreign body even in those cases which showed a true exudate.

Dr. DOUBLEDAY asked Dr. LeWald if he had any pictures of thymus glands. He said the reason he asked this was because he had had some cases of enlarged thymus glands in which no shadow was shown. It was an important matter to know the value of the *x*-ray in determining the presence of an enlarged thymus.

Dr. LEWALD in answer to Dr. Doubleday's question said that in Cincinnati they had had half a dozen cases in which a child when crying and excited at the time of the roentgen examination showed an apparently enlarged thymus gland and at another time the shadow would have entirely disappeared. At the Mayo clinic one of the largest thymus glands that they had found at autopsy had given no *x*-ray shadow. The theory on which we might account for this was that at times the blood supply and the congestion caused the gland to show very distinctly and at other times when the condition was different it would not show in the *x*-ray.

Dr. LYNAH, in closing, stated that while bronchoscopy was practically harmless, there might possibly be some danger in the procedure in a case in which there was a sharp pointed pin or tack in the bronchus, since passing the bronchoscope might cause such a sharp point to rupture into the lung and kill the patient immediately. This was the only danger connected with a bronchoscopy, while if a foreign body were present and were not removed, trouble was sure to follow later.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 18, 1918.

(*Continued from page* 222.)

BACTERIOLOGY.

1. Describe Gram's method in full and explain what is meant by the terms "Gram positive" and "Gram negative."

2. What is meant by a "pure culture" and how do you make it?

3. What is meant by "natural immunity"? What by "acquired immunity"?

4. Name and describe the bactericidal agents in the blood.

5. Differentiate morphologically the cocci from the bacilli and give examples of each.

6. What are the two divisions of staphylococci and what are the essential characteristics of each both as to morphology and their effects on the human system.

7. Describe the *Entameba histolytica* and differentiate it morphologically and pathogenically from bacillus coli.

8. Name the pathogenic organisms that gain entrance to the human body by means of insects and name the insect which is the agent of transmission of each particular organism.

9. To what division of pathogenic organisms does the infecting agent of diphtheria belong and what other organisms are frequently found in the same infected area?

10. What is meant by a "carrier" and what pathogenic organisms are distributed by these agents?

PATHOLOGY.

1. What is caseation? In what disease is it typically found?

2. What tissue changes would be likely to occur in an untreated case of nephrolithiasis?

3. Describe the pathological course of an inoperable case of prostatic carcinoma.

4. What changes, remote and proximal, are likely to occur in cardiac decompensation?

5. Describe the gross and microscopic appearance of tubercular wrist.
6. Describe grossly and microscopically a cancerous liver. Give location of growth to which it is likely to be secondary.
7. What is uremia?
8. Describe a gummatous testicle, grossly and microscopically.
9. Describe the pathology of the cord in tabes dorsalis.
10. What is hypertrophy? Atrophy? Dystrophy? Atony? Hyperemia?

PHYSICAL DIAGNOSIS.

1. How may perforation of the bowel in typhoid fever be recognized?
2. Differentiate rheumatoid arthritis from chronic rheumatism.
3. How may leucemia be distinguished from pernicious anemia?
4. Give symptoms and physical signs of aortic regurgitation.
5. What are the physical signs of acute pericarditis?
6. What are the physical signs of dilatation of the stomach?
7. How may emphysema be distinguished from pleural effusion?
8. How may eclampsia be distinguished from epilepsy?
9. Differentiate acute intussusception from acute dysentery.
10. How may tetanus be distinguished from spinal meningitis?

OBSTETRICS.

1. Describe the placenta.
2. What methods are used to maintain health during pregnancy?
3. What is to be learned by abdominal auscultation in pregnancy?
4. Diagnose pregnancy in the sixth month from spurious pregnancy.
5. What are the causes of abortion? Why is abortion more dangerous than delivery at term?
6. Describe the third stage of labor and give management.
7. Give causes, diagnosis and management of uterine inertia.
8. What is prolapse of the funis? What is precipitate labor?
9. How is a retained placenta to be delivered?
10. What complications in obstetrics justify abdominal section?

ANSWERS.

BACTERIOLOGY.

1. *Gram's method:* "Certain organisms, when stained and afterward treated with a solution of iodine and washed in 95 per cent. alcohol, give up the stain; others retain the color when subjected to this process. These latter organisms, examples of which are the anthrax bacillus and the pneumococcus, are said to be "gram-positive," or to "stain by Gram's method." Those losing the stain are "gram-negative." This method affords a means of measuring the relative permeability of microorganisms to soluble substances. The gram-positive bacteria are those in which the iodine gentian-violet combination penetrates more or less deeply into the interior of the cell; the gram-negative varieties are only superficially affected: (1) Stain in anilin gentian-violet for one and one-half minutes. (2) Wash in water. (3) Treat with Gram's solution (iodine, 1 part; potassium iodide, 2 parts; water, 300 parts) until purplish black, one and one-half minutes. (4) Decolorize with 95 per cent. alcohol for at least five minutes, wash, dry, and mount.

"A contrast stain with fuchsin or 0.5 per cent. solution of safranin may be made if desired (for example, in examining gonorrheal pus); twenty-four-hour agar cultures should be used. For sections, prolong the process."—(Jordan's *Bacteriology.*)

2. A *pure culture* is one that contains only one kind of microorganism.

To make a pure culture: "All that is necessary is to inoculate the liquefied gelatin with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, to pour the liquid on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth."—(*Reference Handbook of the Medical Sciences.*)

3. *Natural immunity* is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by a previous attack of the disease, or (2) by the person being made artificially insusceptible. The chief conditions which give immunity are: (1) A previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

4. *Bactericidal agents in the blood:* (1) There is present normally in the blood serum, *defensive alexins* (substances which act with an amboceptor to produce lysis); (2) *bacterialysins* (substances which kill bacteria with or without lysis); (3) *phagocytes* (chiefly polynuclear leucocytes which consume bacteria); (4) *opsonins* (which so act upon bacteria that they may be taken up by the phagocytes).

5. The *cocci* are spherical; the *bacilli* are rod shaped. *Examples of cocci: Staphylococcus pyogenes, Streptococcus pyogenes, gonococcus. Examples of bacilli: Bacillus typhosus, B. diphtheriæ, B. tetani.*

6. *Varieties of staphylococci:* "According to a number of observers, agglutination experiments point to the existence of at least two races of staphylococci that may be distinguished as 'pathogenic' and 'saprophytic.' The serum of animals injected with the saprophytic race has a much higher agglutinative power for the saprophytic races than for the pathogenic variety, and conversely. In nearly all other respects the two races are almost identical, although most observers agree that only the pathogenic race produces hemolysin and leukocidin."—(Jordan's *Bacteriology.*)

7. The *Entamœba histolytica* is a protozoon, measuring about 15 to 40 microns in diameter; the cytoplasm contains a nucleus, vacuoles, and food particles; it has short pseudopods. It causes amebic dysentery.

The *Bacillus coli* is a bacterium, varying in length from 2 to 4 microns, and in breadth from 0.4 to 0.8 micron; it may occur as a short, oval coccus; it is motile, has spores, but no flagella. It is a regular inhabitant of the intestinal canal, and under certain favoring conditions may cause septicemia, cholera, cystitis, and other pathological conditions.

8. *Pathogenic organisms that gain entrance to the human body by means of insects* are: *Plasmodium malariæ* (by Anopheles mosquito); the organism causing yellow fever (by Stegomyia mosquito); filaria (by Culex mosquito); the organism of dengue (by Culex mosquito); trypanosoma (by Glossina, a tsetse fly); the organism of poliomyelitis (by Stomoxys); the bacillus of typhoid, diphtheria, influenza, trachoma, cholera, dysentery, anthrax, tuberculosis, and the streptococcus of erysipelas the organism of smallpox (by flies); the spirochete of relapsing fever, and the organism of Rocky Mountain spotted fever (by ticks); the bacillus of typhus fever (by lice); *Bacillus pestis* (by fleas).

9. The *Bacillus diphtheriæ* is a pathogenic bacterium, non-motile, non-spore-forming, aerobic, and non-flagellated.

Other organisms frequently found in the same infected area are: The *Streptococcus pyogenes, Bacillus xerasis, Staphylococcus pyagenes,* pseudodiphtheria bacilli.

10. *Carriers* are persons who, though apparently well, harbor within their bodies and distribute to their environment pathogenic bacteria. Diseases thus "carried" are: Typhoid diphtheria, meningitis, tetanus, influenza, pneumonia, malignant edema, Asiatic cholera, dysentery, and perhaps poliomyelitis and other diseases.

PATHOLOGY.

1. *Caseation* "must be regarded as a post-necrotic change in which the necrosed area becomes converted into a structureless cheesy mass of varying consistence, composed of fatty and albuminous granular detritus. It is typically met with in tuberculous lesions, particularly in the lymph-glands, and also occurs in syphilis, in inflammatory lesions, and occasionally in rapidly growing tumors. Caseous matter may be absorbed, or become encapsuled or calcified."—(Hewlett's *Pathology.*)

2. In *untreated nephrolithiasis* there may result: Hydronephrosis, pyelitis, pyelonephritis, pyonephrosis, abscess formation in or near the kidney; the opposite kidney may become hypertrophied; the affected kidney generally shows overgrowth of the interstitial connective tissue with atrophy of the renal cells.

3. "*Carcinoma of the prostate* occurs as a nodular, yellowish-white mass, which projects into the urethra and neck of the bladder, soon becomes ulcerated, and forms deep, ragged excavations. The disease early gives metastasis to the inguinal glands. The growth develops from the glandular cells of the acini of the organ, which form cylindric, elongate, cellular masses, with branched extensions and occasional large cell-nests. The interstitial tissue may be unchanged, or may be very rich in cells, and apparently in active proliferation. The tumor invades the neck of the bladder, seminal vesicles, and rectum, by continuity of tissue, gives metastasis to remote organs, and is rapidly fatal."—(McFarland's *Pathology.*)

4. *Changes likely to occur in cardiac decompensation:* "When compensation fails, the various organs of the body suffer congestion. The lungs are first affected in disease of the left heart (mitral and aortic disease). The capillaries of the pulmonary alveoli become overfull and encroach upon the lumen of the alveoli, or by elongation stretch the alveolar walls and render them inelastic. In either case proper respiration is prevented—a condition which is further aided by the retarded pulmonary circulation. As a result of these conditions, dyspnea (cardiac asthma), cough, and expectoration develop. In extreme cases edematous exudation takes place, and in long-continued cases cyanotic induration of the lung occurs. In such instances there may be continuous cough and respiratory insufficiency. When the right heart fails, the liver, spleen, gastrointestinal mucosa, the kidneys, and the peripheral circulation suffer congestion. The liver may become greatly engorged, and in certain cases (tricuspid regurgitation) actually pulsates with each ventricular systole. The swollen liver cells and the engorged vessels cause obstruction of the biliary capillaries, and consequently produce jaundice. To some extent this may be due to associated congestion of the biliary channels. Congestion of the gastrointestinal mucosa may occasion various forms of gastric or intestinal derangement."—(Stengel's *Pathology.*)

5. *Tuberculous disease of the wrist:* "In instances beginning in the synovial membrane there are formed more or less abundant soft, spongy granulations, which may eventually fill the entire joint-cavity. These are pinkish or whitish in color, and may show gray or yellow spots or tubercles quite plainly. Later this granulation-tissue tends to degenerate, becoming mucoid or breaking down by suppurative or cheesy change. In the early stages the soft tissues of the joint are considerably inflamed and edematous; later they may show ulcerative or necrotic change, and similar alteration may occur in the articular cartilages. Puriform softening of the granulations and the tissues of the joint may lead to the development of *cold abscesses* within the joint, and the latter may eventually burrow to the exterior. In cases progressing unfavorably the joint is greatly disorganized by the advancing necrotic changes. The abnormal productions are either discharged or inspissated, and ankylosis of the joint by fibrous adhesions takes place. The external appearances of tuberculous joints are often quite distinctive. The joint is swollen and boggy, or somewhat elastic to the touch, and usually more or less distorted from subluxation. There is little evidence of acute inflammation. In cases terminating in ankylosis the bones are generally left in faulty position in consequence of the formation of adhesions and the irregular contractions of muscles."—(Stengel's *Pathology.*)

6. *Secondary carcinoma of the liver* "is usually due to the dissemination in the organ of tumor cells from carcinomata of the stomach, intestines, pancreas, or gall bladder. But it may be the result of metastases from the mamma, esophagus, uterus, and various other parts of the body. In secondary carcinoma the cells resemble more or less closely the type of those forming the primary tumor.

"The form in which the carcinoma in the liver occurs varies considerably. Sometimes the tumors are single, but more often multiple; they may be very large, or so small as to be scarcely visible to the naked eye; very frequently numerous small nodules are grouped in the periphery of a larger one. They are sometimes deeply embedded in the liver, sometimes they project from the surface. The liver is frequently and sometimes enormously enlarged. The nodules are usually whitish or yellowish or pink in color or bile-stained, and they are often the seat of hemorrhages, and may become softened at the center, forming cysts filled with degenerated tumor tissue often mixed with blood. The nodules are sometimes hard, sometimes soft and almost diffluent. Fatty degeneration in the tumor is frequent, and may be recognized by yellowish streaks or patches on the sections. Owing to the degeneration and partial absorption of the central portions of the tumors, the nodules on the surface of the liver frequently present a shallow depression at the center. The tumors may be sharply outlined against the adjacent liver tissue, or may merge imperceptibly into it. They may be so large or numerous as to occupy the greater part of the enlarged organ. The neighboring liver cells may be flattened and atrophic. The tumors may press upon the portal vein or its branches, or upon the gall-ducts, and thus seriously interfere with the functions of the organ. Sometimes, however, the tumors are very large and numerous without apparent interference with the function of the liver. *Melanotic carcinomata* sometimes occur in the liver, most frequently as secondary tumors. In some cases, instead of forming separate, distinct nodules, the cancerous growth develops in the form of a diffuse infiltration of the organ, so that the often greatly enlarged liver is irregularly mottled with white and reddish brown masses, and may then somewhat resemble certain forms of chronic interstitial hepatitis."—(Delafield and Prudden's *Pathology.*)

7. *Uremia* is the name given to a group of symptoms (such as headache, drowsiness, stupor, coma, vomiting, twitching of muscles, convulsions) due to retention in the blood of poisons which should have been eliminated by the kidneys.

8. In the *testicle, gummata* "may be single or multiple, small or large. The usual type is the large syphiloma from 1 cm. to 10 cm. in diameter. The smaller, often multiple, lesions give rise to surface irregularity, justifying the term syphilitic nodular orchitis. Large solitary gumma is probably more frequent. Such syphilomata possess fibrohyaline peripheries and frequently necrotic or caseous centers. The points of softening (necrosis) may be multiple. The tunics of the testicle are often involved and fluid may collect in the serous sac. . . . Gummata contain lymphoid and epithelioid cells, with a very slight amount of trabeculæ; occasionally giant cells are present; coagulation necrosis, hyaline degeneration, and fatty change may cause the center to resemble caseous material."—(Coplin's *Pathology.*)

9. In *locomotor ataxia* the posterior columns of the spinal cord and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upwards from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial

nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

10. *Hypertrophy* is an increase in the size, weight and functional activity of a part beyond the limit of health and due to an orderly enlargement or multiplication of its normal constituents.

Atrophy is a decrease in the amount of tissue, owing to diminution in size (simple atrophy) or number (numerical atrophy) of the cells of which it is composed.

Dystrophy is disordered nutrition (either diminished or perverted).

Atony is the lack of tone or contracting power or vigor of a tissue (generally used of muscle tissue), also undue relaxation.

Hyperemia is excess of blood in the dilated vessels of a part; it may be active (or arterial) or passive (or venous).

PHYSICAL DIAGNOSIS.

1. *Intestinal perforation in typhoid fever:* Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dullness disappear, and leucocytosis may be present. The treatment is surgical; laparotomy, with suture of the intestine, should be done as soon as possible. In the meantime opium (or preferably morphine) should be administered.

2. *Rheumatoid arthritis and chronic rheumatism:* "It is difficult and readily may be impossible to distinguish between arthritis deformans and chronic rheumatism in the early stages. In more advanced cases the former presents greater deformity of the joints, while rheumatism tends rather to ankylosis with comparatively slight alteration in shape, and, moreover, is likely to attack a larger number of articulations than arthritis deformans. It is proper to state that by some writers arthritis deformans is regarded as an advanced stage of chronic rheumatism."—(*Reference Handbook of the Medical Sciences.*)

3. *Leucemia* may be differentiated from pernicious anemia by an examination of the blood. In *leucemia* there is a marked increase in the number of leucocytes, and in the spleno-medullary form myelocytes are observed; in the lymphatic form the lymphocytes are much increased. In *pernicious anemia* the red cells are notably diminished in number, the hemoglobin is relatively increased, the red cells vary in shape, size, etc.; the leucocytes are not increased, but (occasionally) may be diminished.

4. *Symptoms of aortic regurgitation:* "So long as the cardiac hypertrophy is just sufficient to compensate for the valvular condition, there are no symptoms, but as the muscle walls continue to increase symptoms of cardiac hypertrophy present themselves, such as forcible cardiac action, with marked pulsation of all the vessels, including the capillaries, the characteristic forcible and receding pulse ('water-hammer pulse' or 'Corrigan pulse'), headache, insomnia, tinnitus aurium, congestion of the eyes and face, etc. Precordial pain is usually present in aortic disease. It may be a sensation of constriction in the cardiac region or it may consist of sharp, shooting pains extending to the arms—anginoid attacks. As soon as the slightest failure of compensation occurs, the cardiac action becomes excessive and distressing. Palpitation is present and causes anxiety and fear on the part of the patient.

When there is complete rupture of compensation, there develop, either gradually or rapidly, dyspnea, increased on exertion, cough, cyanosis, hepatic enlargement, renal congestion with scanty, albuminous urine, ascites, and dropsy. If mitral insufficiency is now superadded, general venous stasis and death rapidly follow. Sudden death is most frequent in this form of valvular heart disease."

Physical signs of aortic regurgitation: "Inspection shows that the cardiac impulse is forcible and displaced downward and to the left. The pulsation is visible far beyond the normal apex. *Palpation* confirms inspection. It may at times serve to detect a diastolic thrill over the base of the heart and the adjacent large vessels. The Corrigan pulse and the capillary pulse are recognized by palpation. *Percussion* serves to demonstrate an increase in the area of cardiac dullness downward and to the left. Occasionally it is increased upward and to the left of the sternum as the result of hypertrophy of the left auricle. *Auscultation* reveals characteristic alterations in the heart sounds. The first sound is forcible; the second sound is replaced or associated with a churning, rushing, or blowing murmur of low pitch, well heard at the second right costal cartilage (aortic area), but most distinct at the junction of the sternum and the fourth left costal cartilage. It is diastolic in time, and is transmitted downward and toward the apex. A presystolic rumbling murmur (Flint murmur) may occasionally be heard over a limited area at the apex."—(Hughes' *Practice of Medicine.*)

5. *Physical signs of acute pericarditis: "Inspection* during the early stage shows excited cardiac action as evidenced by the impulse. During the effusion stage the impulse is feeble, undulatory, or absent; it is usually displaced upward, very rarely downward, the precordium bulges, and the abdomen protrudes when the effusion is large. *Palpation* during the early stage serves to detect an excited or tumultuous impulse, and in very rare instances pericardial friction fremitus. During the effusion stage the impulse is feeble or absent, and when present is considerably displaced. Tenderness may be elicited. *Percussion* is normal in the beginning of the disease, but as the effusion forms the cardiac dullness becomes enlarged vertically and laterally. If the accumulation of fluid is considerable the dullness assumes a triangular shape, with the base on a line with the sixth or seventh rib, extending from the right of the sternum to the left of the left nipple, and the apex at the sternal attachment of the second rib or higher. The shape of the dullness is sometimes altered by changing the position of the patient.

Auscultation at the onset reveals excited cardiac action and usually an exocardial murmur or friction sound, synchronous with the cardiac sounds and uninfluenced by respiration, but often increased by pressure with the stethoscope. Later, as the effusion forms, the cardiac sounds are feeble and deep-seated at the apex, becoming louder and distinct toward the cardiac base. The friction sound is sometimes heard at the base. As absorption progresses, the friction sound returns, being replaced shortly by the normal heart sounds."—(Hughes' *Practice of Medicine.*)

6. *Physical signs of dilatation of the stomach: "Inspection.*—The abdomen may be unduly prominent. In some cases the outlines of the enlarged stomach are distinctly visible. Peristaltic waves extending from left to right are frequently seen, especially in stenotic dilatation. *Palpation.*—When the stomach-walls are sufficiently tense, the boundaries of the organ may be determined by palpation. In many cases of obstructive dilatation a tumor can be felt at the pylorus. *Percussion.*—When the stomach contains fluid, an area of dullness is found at the level of the umbilicus, or below it when the patient is erect, but not when he is lying down. This area of dullness also disappears upon the complete evacuation of the stomach. After artificial inflation of the stomach with air or carbonic-acid gas percussion reveals an increased area of gastric tympany. *Auscultation.*—The detection of splashing sounds over the stomach in the morning before breakfast or seven hours after a Riegel test-meal points to dilatation. *X-rays.*—Skiagraphs taken after the ingestion of large quantities of bismuth subcarbonate suspended in buttermilk or porridge have proved of great value in the diagnosis of gastrectasis. *Examination of the Stomach-contents.*—The detection of remnants of food in the stomach in the morning after a simple supper renders the diagnosis of severe motor insufficiency certain, and that of dilatation highly probable."—(Stevens' *Practice of Medicine.*)

7.

Empyema.	Pleurisy with Effusion.
1. Usually a history of previous disease, as pleurisy, phthisis, general debility, etc.	1. History of an acute attack following exposure to wet, cold, etc.
2. Constitutional symptoms well marked.	2. General condition remains quite good.
3. Temperature often reaches 105°.	3. Temperature seldom over 102°.
4. Chills and profuse sweats common.	4. No chills or sweats.
5. Fluid remains unless it is withdrawn.	5. Fluid disappears under appropriate medical treatment.
6. Exploring needle withdraws pus.	6. Exploring needle withdraws serum.
7. Whispered pectoriloquy sometimes heard below the level of the fluid.	7. Absence of voice sound below the level of the fluid.

—(Cutler's *Differential Diagnosis.*)

8. *Eclampsia* is a vague term. Assuming that a uremic convulsion is understood:

Uremic Covulsions	Epilepsy.
1. History of Bright's disease.	1. History of epilepsy.
2. Edema.	2. No general edema.
3. Convulsions migratory in character.	3. Convulsions general—tonic then clonic.
4. No change in pupils.	4. Dilated pupils follow spasm.
5. No biting of tongue.	5. Tongue bitten.
6. Waxy countenance.	6. Countenance cyanotic.
7. Albumen and casts in urine.	7. Urine normal.
8. Temperature low.	8. Temperature elevated.
9. Deep coma follows convulsions.	9. Mild coma or sleep.
10. No initial cry or pallor.	10. Initial cry and pallor.

—(Cutler's *Differential Diagnosis.*)

9. In *acute intussusception*, the patient is usually an infant, child, or young adult; a sausage-shaped tumor can generally be felt in the right iliac or umbilical region; the stools are mucous and bloody; there are abdominal pains, constipation, and vomiting.

In *acute dysentery*, there is great tenesmus and diarrhea; there is no vomiting, and no abdominal tumor; the stools are very frequent, and may contain the ameba coli or some bacilli, with blood and mucus.

10.

Spinal Meningitis.	Tetanus.
1. No traumatic history.	1. History of traumatism.
2. Face not peculiar.	2. Risus sardonicus.
3. No jaw symptoms.	3. Lockjaw.
4. Great pain on motion.	4. Intense hyperesthesia.
5. Spasm produced by attempts to move.	5. Spasm caused by external irritation.
6. Paralysis follows spasms.	6. No paralysis.
7. Temperature elevated.	7. Temperature nearly normal.

—(Cutler's *Differential Diagnosis.*)

OBSTETRICS.

1. At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound. It is *formed*, partly from the mucous membrane of the uterus, and partly from the chorionic villi. Its *functions* are: (1) To supply nourishment to the fetus; (2) to act as a respiratory organ for the fetus; (3) to act as an excretory organ for the fetus; (4) it is also supposed to provide an internal secretion. Its *usual location* is on the anterior or posterior wall of the uterus, near the fundus.

2. The patient should be instructed fully in the hygiene of pregnancy, by which is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food at regular hours, clothing not too tight, especially about the abdomen and breast; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed.

3. By *abdominal auscultation in pregnancy:* (1) The fact of pregnancy can be ascertained; (2) the fact that the fetus is alive can be ascertained; (3) the position of the fetus can be diagnosed; (4) the existence of twins may be diagnosed; (5) the condition of the fetus can be ascertained; (6) some observers assert that the sex of the fetus can be ascertained.

4. *Pregnancy at the sixth month* is diagnosed by the presence of the fetal heart sounds, and active and passive fetal movements. In no other conditions are these present.

In *spurious pregnancy* the uterus is not enlarged, there is no fetal heart sound; fetal movements are absent, and the administration of a general anesthetic causes the "tumor" to collapse.

5. *The causes of abortion and premature labor* may be briefly enumerated as follows: "(1) Any pathologic condition of the ovum, membranes, or placenta, such as apoplexies, cystic degeneration of the chorionic villi, and cellular infiltration of the placenta. (2) Certain general diseases of the mother, including syphilis, typhoid fever, the exanthemas, and conditions interfering with proper aeration of the blood, as pneumonia and valvular heart disease; various systemic poisons, as malaria, lead, and arsenic; certain blood diseases, as grave anemia and leukocythemia; various local conditions, such as metritis, salpingitis, and ovaritis, cystitis, appendicitis, and placenta prævia. (3) Diseases of the father, such as syphilis, phthisis, and nephritis, in which the spermatozoa are diseased or of lessened vitality. (4) Death of the fetus from any cause. (5) Traumatism, as from a fall, a blow, or a kick on the abdomen. (6) Spasmodic muscular action, as in chorea, uncontrollable vomiting or coughing, convulsions of any kind. (7) Reflex causes, as violent emotion or mental shock. When the uterus shows a tendency to contract under the slightest stimulus (irritable uterus), any trivial cause, such as a long walk, a hot bath, or even the sight of another woman in labor may result in abortion. (8) Criminal abortion, caused by the use of drugs, vaginal and uterine injections, and the introduction of an instrument into the uterus."—(*Pocket Cyclopedia.*)

Abortion is more dangerous than delivery at term, because: (1) The patients frequently make light of the condition and do not take the same care of themselves as they would after a confinement; (2) the liability to sepsis and hemorrhage is greater; (3) subinvolution and uterine displacements are more liable to occur.

6. *Third stage of labor:* "By the time the child is fully expelled the placenta is often separated from the uterine wall and lying loose in the now contracted uterine cavity. The womb may be felt as a hard, irregularly globular ball above the pubes. There may be an interval of one-quarter or one-half of an hour's rest from pains, if the case be left entirely alone. Then, sooner or later, gentle pains again come on, the placenta is doubled vertically, the fetal surface of one half in apposition with that of the other, and the organ protruded endwise into the vagina, from whence it is, by other slight pains, finally expelled, together with some blood, remains of liquor amnii, membranes, etc. The womb now contracts into a distinctly globular, hard mass, no bigger than a cricket-ball, thus effectually closing the uterine bloodvessels and preventing hemorrhage, which last is further stopped by coagulation of blood in the mouths of the open blood-channels."—(King's *Obstetrics.*)

Management: In the *third stage of labor* the physician should seize the fundus of the uterus through the abdominal wall and knead and rub it until it contracts vigorously; then he should press it down in the direction of the axis of the pelvic inlet. This should last for about a quarter of an hour after the child is born. The placenta, after it is expressed, should be carefully taken by the physician so as to be sure that it is *all* expelled; at the same time care must be taken that no particle of membrane remains behind. Fuidextract of ergot may be administered.

7. *Uterine inertia* may be *caused* by: Debilitated constitution, exhausting disease; uterus weakened because of congenital malformation, inflammation, or too frequent child-bearing; adhesions to neighboring structures; tumors of the uterus or neighboring tissues; distention of the bladder or intestine; displacement of the uterus; premature escape of the liquor amnii; pregnancy in an old primipara; hydramnios; twin pregnancy; fright or mental emotion.

The cervix dilates slowly or not at all; if the membranes are ruptured the fetus makes little or no advance; the woman shows evidences of fatigue and may be anxious or restless; the skin gets dry, the pulse small and rapid, the temperature elevated, the tongue dry and furred, nausea and vomiting may supervene, and delirium and coma may follow.—(From Webster's *Obstetrics.*)

Treatment consists in removing the cause if possible; the bladder and bowel should be emptied; opium, morphine and chloral may be given so that the patient may get a little sleep, at the same time food may be administered; the uterus may be massaged through the abdominal walls; hot vaginal douches are sometimes helpful; the vagina may be distended with a rubber bag; if the membranes are ruptured, a Champetier de Ribes bag may be placed in the lower part of the uterus; an anesthetic may be necessary; quinine, strychnine, and ergot have been recommended by some, and condemned by others; the newest remedy is pituitrin, which may be injected into the muscles in doses of from 1 to 1½ c.c., provided that the cervix is dilated and that there is no obstruction to delivery.

8. *Prolapse of the funis* is the condition in which the umbilical cord hangs down alongside of or in front of the presenting part of the fetus.

Precipitate labor is a labor in which the child is delivered with unusual rapidity.

9. *Delivery of retained placenta:* "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exists, at a point where the placental border is thick, and then passed to and fro, transversely, through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and the subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily, until everything has come away."—(King's *Obstetrics.*)

10. *Cesarean section.*—"*Indications:* The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the '*positive*' indication for cesarean section; there is nothing else to be done. Flat pelves having a conjugata vera of 2¼ inches or less, and justo-minor pelves with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible; but cesarean section is agreed upon to *save the life of the child;* (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(King's *Obstetrics.*)

In addition, abdominal section may be required for abdominal tumors, for suppurative peritonitis, for ectopic pregnancy, and in puerperal sepsis.

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

GAS POISONING IN WARFARE.*

A STUDY OF THE EFFECTS OF SO-CALLED MUSTARD GAS UPON THE UPPER RESPIRATORY TRACT.

BY GERARD HUTCHISON COX,

MAJOR, MEDICAL CORPS, U. S. A.

EARLY in 1915 a new type of warfare was introduced on the Western front with the launching of the first cloud gas attack against the British. Suddenly confronted with waves of poisonous gas, carried along by the wind, the troops were absolutely helpless, except for the protection afforded by their pocket handkerchiefs, saturated with any available liquid material, not infrequently urine.

It was not long before gas masks were invented, and these now form an essential part of the equipment of all troops operating in the front area.

Cloud Gas Attacks.—The gas is taken to the front-line trenches, compressed in steel cylinders, which are placed in the bottom of the trenches and carried over the parapets by pipes. Cloud gas attacks are dependent upon the direction and velocity of the wind, and are made when there is a strong, steady wind blowing at the rate of from four to eight miles an hour in a direction from the enemy lines toward those of the troops attacked. In most instances cloud gas attacks have been made at night.

At first, chlorine was employed; later it was mixed with phosgene. Both are heavier than air, and therefore roll along the ground, entering trenches, shelters, crater holes, and unprotected dug-outs.

There are certain disadvantages to cloud gas attacks which have led to their abandonment and the substitution of other methods. In the first place, if the wind suddenly changes, the gas is blown back upon the enemy. In the second place, the danger of leakage from the containers is considerable. Then, too, there is the ever-present danger of a shell fragment striking the gas cylinder and thus poisoning the gas operators.

Consequently, cloud gas attacks have been abandoned, and gas shells or gas projectiles, used instead.

Gas Projectiles.—In a gas projectile a part or the whole of the explosive charge is replaced by a liquid which is converted into gas by the explosion of the charge. There are various kinds, viz.: shells, trench mortar bombs, hand grenades, and projectors. Gas shells are frequently not used alone. For example, during a bombardment with high explosives and shrapnel a certain number of gas shells are mixed with the high explosive shells, thus masking the gas attack. The odor from the gases now used is very slight, often almost negligible. The first intimation of a gas attack may be a shell which sounds like a "dud," *i.e.* a high-explosive shell which strikes the ground and fails to explode. In the case of the gas shell, as part of the charge has been replaced by a liquid the noise of the explosive is very much less violent, and thus the first hint of a gas attack is given.

Alarms of various types are immediately sounded, and gas masks are put on at once. The slightest delay on the part of the men in adjusting their respirators may mean serious disability or even death.

Gas Masks.—The first gas mask adopted by the British is known as the P. H. helmet. It fits over the head, and is fastened around the neck under the tunic. (See Fig. 1.) As the material from which this helmet is manufactured cannot be saturated with a sufficient number of chemicals to make it impervious to all enemy gases, its use has been abandoned and the box respirator substituted. The latter is shown in Figs. 2 and 3, and consists of a box packed with chemicals, and connected by a rubber tube with an impervious mouthpiece or mask. The inspired air enters through a valve at the bottom of the box, while the expired air escapes through a valve connected with the rubber breathing tube. The wearer's nose is closed by a clip inside the mask, which prevents the air inside the face piece being breathed back and forth through the nostrils. The mask is also provided with two eyepieces, which are cleaned by means of folds in the material. This box respirator is carried in a suitable canvas container, and is a thoroughly trustworthy and efficient protection against all poisonous gases used by the enemy. Fig. 4 shows a picture of a captured German gas mask.

In the British army, horses are provided with gas masks when they are sent to the vicinity of the trenches with ammunition and supplies. These animals are said to stand a higher degree of concentration of poisonous gases without great damage than is the case with human beings. It is not considered necessary to protect their eyes.

The horse respirator consists of a flannelette bag with a canvas mouthpiece which fits into the animal's mouth. Fig. 5 shows the mask worn in the alert position. Fig. 6 shows the mask as worn during a gas attack. This respirator does not interfere with the use of the bit and reins.

*Published with the consent of the Surgeon-General, U. S. A. This paper was written in France in April, 1918.

Classification of Poisonous Gases.—For our purposes, the gases used by the enemy may be divided into four main groups. It is obviously not permissible, for military reasons, to give a complete list of all enemy gases, or to state the sources from

Fig. 1.—P. H. helmet.

which some of the information contained in this paper is derived.

(1) *Lacrymator* or *tear gases*, of which benzyl bromide may be taken as a type.

(2) *Eye and lung irritant*—of these perhaps the best known is chlorine.

(3) *Lung irritant and asphyxiant*—phosgene.

(4) *Eye, lung, and skin irritant*—"mustard gas."

Pathology and Symptomatology of the Four Types of Gases.—In this connection it is important to remember that a shell gas—for example, phosgene—is seldom used alone, but is generally combined with some other gas or gases, perhaps mustard. Hence the symptoms exhibited by the individual who has been poisoned vary, as one or other of the gases predominates in the mixture.

(1) The lacrymator gases, or eye irritants, produce excessive lacrymation, photophobia, and palpebral spasm. In high concentration they cause irritation of the throat, and nausea; needless to say, they are never fatal.

(2) A typical case of poisoning by chlorine gas, which may be taken as an example of eye and lung irritants, exhibits the following phenomena: Lacrymation, spasm of the glottis, choking sensations, cough, and dyspnea are followed by headache, nausea, and vomiting.

In a severe case the man passes into a state of asphyxial cyanosis, with mental failure and loss of consciousness. The breathing is rapid, labored, and interrupted by spasmodic coughing. At first, the face is cyanotic; as the circulation fails, a gray pallor ensues. Finally, death results.

The writer has not had an opportunity to observe the post-mortem appearance in chlorine gas poisoning, which are said to be as follows: The trachea and bronchi are deep red and congested. There is often a thin, serous exudate in the lungs. Petechial hemorrhages are present on the surface of the lungs, heart, and stomach. Pleurisy and bronchopneumonia, with purulent secretion in the bronchi, are usual findings.

(3) Asphyxiant and lung irritant. Phosgene represents this type of gas. The eyes are very slightly, if at all, affected by the poison, which is characterized by its delayed action on the heart and lungs.

Major Moore of the Royal Army Medical Corps told me that earlier in the war many a man who had been gassed with phosgene, apparently lightly, had started off to the aid post with his heavy pack on his back and rifle over his shoulder. One hour later he falls down dead from heart failure. For this reason, soldiers poisoned with phosgene are now carried back on stretchers, and not allowed to walk.

Unfortunately, the writer has no autopsy notes at his disposal on phosgene poisoning.

(4) Eye, lung, and skin irritant—mustard oil. The symptoms and pathology of mustard gas poisoning will be described later.

This study is based upon a series of 362 cases admitted to No. 1 General Hospital (Presbyterian, U. S. A.), British Expeditionary Force, in two convoys. In the first convoy 32 cases of mustard gas poisoning were examined by the writer. In the second group there were probably a few cases showing the combined action of mustard gas and phosgene.

In a base hospital, where many of the patients are evacuated after short intervals, it is manifestly impossible for one man to examine the upper air tracts of such a large number of patients. After consultation with the commanding officer, Major Darrach, a questionnaire was drawn up and given

Fig. 2.—Box respirator or mask, in "alert position."

to the medical officers in charge of the hospital wards, who filled in the required data.

The writer wishes to acknowledge his indebtedness to the commanding officer and medical officers of this unit for their cooperation and assistance

at a time when they were extremely busy with the care of large numbers of casualties.

In addition to taking many of the histories, the writer has examined personally the eyes, nose, pharynx, larynx, and upper trachea of over 100 cases of mustard gas poisoning.

Fig. 3.—Box respirator applied.

The Questionnaire:

Patient's name.
Date of admission.
When gassed—day or night attack.
Kind of gas.
Interval before onset of symptoms.
First symptom.
Was gas mask applied, and how soon?
Walked or carried to aid station?
How soon after being gassed were you seen by a medical officer?
Was the gas smelled? Yes. No.
Kind of treatment given on way to base.

Symptoms (underline symptoms complained of):

Eye—Burning, photophobia, lacrymation, swelling of the lids, temporary loss of vision.
Ear.
Nose—Burning, sneezing, discharge.
Throat—Choking sensation, tickling, cough, hoarseness, partial or complete loss of voice.
Bronchi and lungs—Cough, dyspnea, pain in chest, sputum.
Burns of skin (location and degree).
Gastrointestinal tract—Nausea, vomiting, diarrhea, anorexia.

Physical Examination:

Eyes.
Ears.
Nose.
Pharynx.
Larynx.
Trachea.
Heart.
Lungs (brief report).
Skin lesion.

Treatment at No. 1 General Hospital.

The following statistics are based upon a series of 330 cases of mustard gas poisoning.

The first and most striking observation is that in mustard gas poisoning there is always an appreciable interval between the time when the individual is gassed and the onset of his symptoms. In 37.6 per cent. this latent period varied from 8 to 12 hours; in 27 per cent. it was from 4 to 8 hours; in 12.6 per cent., 12 hours or longer; 9.6 per cent. developed symptoms in 2 hours or less; while 1 per cent. of the soldiers showed the first sign in from 2 to 4 hours; one man claimed he had no symptoms for 48 hours and another for 36 hours.

The question as to the first symptom complained of elicited the following replies:

	Per cent.
Burning and smarting of the eyes	47.6
Lacrymation	18.6
Vomiting	9.6
Nausea	4.0
Irritation of the throat	3.6
Cough	1.6
Choking sensations in the throat	1.3
Diarrhea	0.6
Headache	0.6
Sneezing	0.3

Two hundred and twelve men, or 64.4 per cent., said they applied their gas masks immediately upon being bombarded with gas shells. Twenty, or 6.3 per cent., stated that they put on the mask immediately after smelling the gas; 12 per cent. did not apply the mask, while 15 per cent. wore the mask at intervals.

Fig. 4.—German gas mask.

Ninety-three per cent. of the men walked to the aid stations, while 6 per cent. were carried on stretchers.

It was stated by 86.1 per cent. that they smelled the gas, which they compared to the odor of mus-

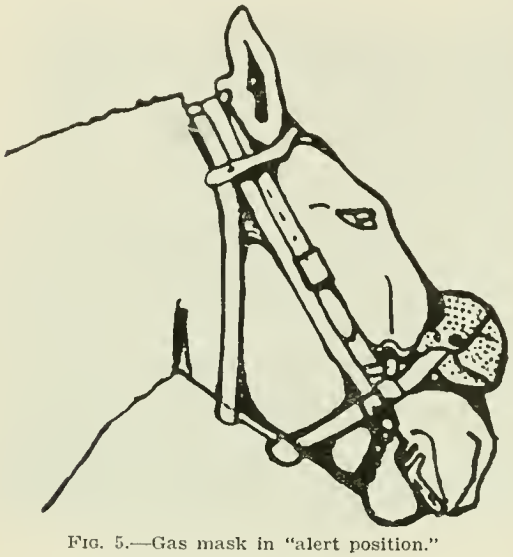

Fig. 5.—Gas mask in "alert position."

tard, pineapple, garlic, or onions; 13.1 per cent. failed to notice any odor. In some cases this may be explained by the promptness with which the respirators were put on when the command was given.

At the casualty clearing stations and at the hospital trains, 90.1 per cent. had their eyes treated by irrigation or bathing, while 9.2 per cent. had cold packs applied. One officer told me he was given a perforated inhaler resembling the Robinson zinc inhaler used by us.

The following table gives the percentages of cases showing symptoms referable to the various organs:

Eye Symptoms.—98.5 per cent. showed one or more of the following symptoms: Burning, photophobia, lacrymation, swelling of the lids, temporary loss of vision.

Ear Symptoms.—5.2 per cent.

Nose.—Burning, sneezing, discharge, 71.1 per cent.

Throat.—Choking sensations, tickling, cough, hoarseness, partial or complete loss of voice, 93.3 per cent.

Bronchi and Lungs.—Cough, dyspnea, pain in chest, sputum, 8.6 per cent.

Cutaneous Burns.—First degree, 5.1 per cent.; second degree, 0.9 per cent.; other burns (degree not stated), 11.4 per cent.

Gastrointestinal Tract.—Anorexia, nausea, vomiting, diarrhea, 80.3 per cent.

Smell.—Of 92 men questioned as to the loss of smell and taste, 82 noted a loss of the sense of smell; 62 lost their taste. The loss of smell and taste is apparently temporary, both usually returning in a few days.

Examination of the Eyes.—Practically all cases showed a conjunctivitis varying in intensity from a mild inflammation to a severe form, with redness and swelling of the lids, accompanied by a purulent secretion and excoriation of the skin at the inner and outer canthi. One severe eye inflammation had some elevation of the epithelium of the bulbar conjunctiva, while many cases exhibited photophobia out of proportion to the amount of inflammation present. Redness of the mucosa of the lower lids often persisted after the subsidence of the redness of the bulbar conjunctiva.

The average mild case was seen walking about on the streets with an eye-shade seven or eight days after being gassed. In a couple of weeks many were almost normal, and able to dispense with their eye-shades.

No corneal lesions were seen in this series. Other observers have noted superficial corneal ulcers in rare instances.

Examination of the Ears.—Ear complications are rare, about 5 per cent. The most common is acute tubal catarrh, with tinnitus, caused by the inflammation extending from the mucous membrane of the rhinopharynx to the Eustachian tube. One man, who presented a chronic purulent otitis media, with a large central perforation, and some pain in the ear, stated that the present exacerbation of his old ear trouble dated from the gas attack.

In cases of perforated ear drum, of course, the gas enters directly into the tympanic cavity, where it produces an inflammatory reaction, unless the ear is protected by cottonwool in the canal.

Another case of chronic purulent otitis media was admitted with considerable pain and some mastoid tenderness, which cleared up with irrigations. A third case showed a myringitis, with a large bleb on the tympanic membrane.

Nose, Pharynx, Larynx, and Trachea.—The conditions found on examination of these organs were almost identical in the great majority of cases. There were redness and swelling of the mucous membrane of the nose, pharynx, epiglottis, larynx, and trachea, varying in degree only, and associated with increased secretion. The mucosa in some cases was slightly reddened, while in the more severe cases it was fiery red.

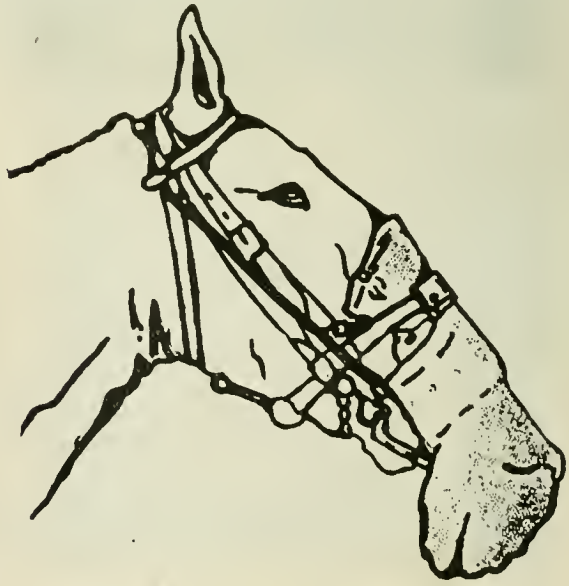

Fig. 6.—Mask as worn during a gas attack.

In the nose, the entire mucous membrane was involved, particularly that covering the inferior turbinates and nasal septum, which were often in contact. The nasal secretion was usually increased in quantity.

In the pharynx, the mild cases showed redness of the posterior pharyngeal wall, with swelling and redness of the follicles. The more severe cases exhibited, in addition, inflammation of the tonsils, tonsillar pillars, and uvula. Lateral pharyngitis was common. The mouth and tongue were unaffected. One case showed swelling and reddening of the lingual tonsil. One man had a grayish slough on the posterior pillar of the tonsil.

In the larynx, as already stated, the majority of cases showed a mild or moderate degree of laryngitis, the entire larynx being uniformly reddened. Reddening and inflammation of the epiglottis were quite uniform, and seemed distinctive of this form of laryngitis, in contrast to the usual findings in acute catarrhal laryngitis as seen in civil life.

In some of the more severe forms, the redness and edema of the false vocal cords was considerable, and out of proportion to the amount of involvement exhibited by the true cords.

Fig. 7.—Typical mustard gas burn of back. (Lieut. Cunningham's case.)

Four cases showed spots of superficial necrosis or ulceration of the laryngeal mucosa. In one patient these necrotic spots were seen on the false vocal cords and on the right true cord. A second case had a superficial white necrosis involving the margin of the epiglottis for a considerable area. A third man showed a superficial small necrotic spot on the left arytenoid cartilage, of which no trace could be discovered on laryngeal examination one week later. In two other patients the margins of the true vocal cords were slightly irregular in outline, evidently due to a slight superficial ulceration of the epithelium.

In a number of men who developed "late aphonia," 4 to 6 days after being gassed, the laryngeal examination showed a picture similar to that of the cases of early aphonia already described, viz., more or less severe inflammation of the larynx. None of these late cases exhibited any areas of superficial necrosis.

Examination of the Heart.—The cases examined here did not show any heart lesions, with the exception of a patient of Captain Peters', who had a slightly dilated heart, accompanied by tachycardia and extrasystole.

In 100 cases, mostly from the medical wards, bronchitis was present in 30 per cent. In the last convoy of about 340 cases admitted to this hospital there was not a single case of pneumonia. It is possible, of course, that pneumonia cases may have been kept at the casualty clearing stations.

Most of the cases of bronchitis clear up quickly, although the after effects on the lungs, such as dyspnea on exertion, are often protracted. One man admitted to this hospital at an earlier date died from lobar pneumonia.

Skin Lesions.—As stated above, 20.9 per cent. of the cases presented cutaneous burns, and of these 5.1 per cent. were first-degree burns and 0.9 per cent. second degree. In the remaining 11.4 per cent. the character of the burn was not stated.

When first seen at the casualty clearing stations, many cases are said to have a dull red rash, which disappears on pressure, and which tends to persist in patches. In the center of these reddened areas blisters are often observed.

The scrotum, back, inner sides of the thighs, and other moist surfaces, are the usual sites for burns. Two of my patients had burns of the buttocks from sitting on latrines.

Fig. 7 shows a typical burn of the back. This man was admitted to Lieutenant Cunningham's ward March 15. He had been shelled with mustard gas shells off and on for six nights. When first observed he presented three small blebs on the back surrounded by a small area of erythema. The burn was treated with 1 per cent. soda bicarbonate solution. On March 20 the erythematous area increased to about twice its original size, the margins became sharply defined, and the blisters broke down. The reddened area then assumed a slightly brownish tinge.

A late bronzing of the skin, particularly of the face, neck, forearms, and hands, was observed in a number of cases, coming on from four to five days after the gas attack. The appearance is not unlike the bronzing of Addison's disease.

Phosgene poisoning differs from mustard gas poisoning as follows: (1) The eyes are very slightly, if at all, affected by phosgene poisoning. Mustard is an intense eye irritant. (2) Phosgene produces cyanosis of the skin, while mustard gas causes a cutaneous redness, with bronzing after a few days. (3) Phosgene is not a skin irritant. Mustard is a severe skin irritant. (4) Phosgene is said never to produce a pseudomembrane in the trachea and bronchial tubes. Mustard, on the contrary, as will be shown later, may cause a complete cast of the bronchial tree. (5) Phosgene is apt to produce edema of the lungs. Mustard is associated with broncho- or lobar pneumonia. Both poisons sometimes cause emphysema.

Before leaving the symptomatology of mustard gas poisoning let us consider for a moment a typi-

cal history of the type of case admitted to the base hospital, which is somewhat as follows:

The soldier was bombarded with gas shells during the night for several hours. Perhaps he was slow in putting on the gas mask, perhaps he took it off too soon. Or, again, he may have been shelled for several nights in succession, and the trenches, shell holes, bushes, etc., have then a certain amount of gas lying about, particularly if there is very little wind.

Some time after the bombardment ceases the individual goes to sleep feeling perfectly well; the following morning, *i.e.* 6 to 12 hours later, he is seized with intense burning and watering of the eyes, accompanied by great photophobia and swelling of the lids. There is usually some irritation and discharge from the nose. Or, again, the first intimation that he has been gassed may be an attack of nausea and vomiting. There is apt to be some irritation of the throat, with cough and dyspnea upon exertion; 12 to 36 hours later a partial or almost complete aphonia ensues. Diarrhea is rare. Cutaneous blisters are fairly common about the moist surfaces of the skin, inner sides of the thighs, scrotum, back, etc.

Such is the usual picture presented by the ordinary mild case of mustard gas poisoning.

Temperature in Mustard Gas Poisoning.—In my own wards there was an occasional mouth temperature of 99° F., which quickly fell to normal. Most of my cases, however, had normal temperatures.

Post-Mortem Findings in Mustard Gas Poisoning.—Major Brewer and Lieutenant Allison of this unit both had opportunities of observing autopsies at British casualty clearing stations in the vicinity of Ypres, in the summer and fall of 1917.

The post mortems observed by Major Brewer were on two men of a group caught without their masks, and hence they were severely gassed. Both autopsies showed the following: A grayish pseudomembrane representing a superficial necrosis of the mucosa of the larynx, trachea, and bronchi to their first ramifications, making a veritable cast of the entire bronchial tree; an extreme bronchopneumonia of both lungs was also present.

The three autopsies observed by Lieutenant Allison were upon men who died within 48 hours after being gassed. They presented practically the same findings, viz.: all died of bronchopneumonia. All three had excessive cutaneous blisters. The lungs presented diffuse bronchopneumonia with a few collapsed areas due to the bronchioles running to these areas being plugged by bronchial casts. The trachea and larger bronchi showed practically complete casts of the tubes. Here and there these casts were adherent to the superstructure. The casts themselves were formed by desquamated epithelium. The finer bronchioles showed the same thing, but to a slighter degree; in places there was simply an intense inflammation of the mucous membrane. The spleen and kidneys were in a state of active congestion.

Pte, P. B., age 30 years. (Autopsy by Lieut. Cunningham, who kindly furnished me with the following notes).

Clinical Notes.—January 30, 1918. Admitted to Casualty Clearing Station. Marked conjunctivitis. Cough. Pain in chest. February 3, 1918. Admitted to No. 1 General Hospital. Gassed four days ago. Very marked conjunctivitis. Temperature on admission normal. Showed rough breathing at both apices. No dulness. A few rales. Pharyngitis and laryngitis. Tenderness in epigastrium. No burns. Within twenty four hours developed temperature of 104, with signs over left lower lobe. Pulse 130 to 160, growing more rapid. Sputum smear and culture showed influenza bacillus. February 8, 1918. Patient died at 7:45 p. m.

Autopsy Notes.—The body is that of a well developed and well nourished man about 28 or 30 years of age. There is a slight palpebral swelling and injection of the ocular conjunctivae. The skin of the arms, particularly the inner humeral region, presents a bluish pink mottling. Slightly enlarged axillary lymph glands; epitrochlear palpable on right side, inguinal glands small. Abdomen somewhat distended and tympanitic. No free peritoneal fluid.

Lungs.—There is over the lower lobe anteriorly what appears to be a thin yellowish white exudate—the lobe is solid throughout, of a reddish color. The upper and lower lobes are adherent with a fresh exudate. The upper lobe crepitates throughout, except for a very thin margin along its approximation to the lower lobe. Section shows the lower lobe to be very granular and grayish pink in color. The upper lobe is congested and somewhat oedematous. Purulent exudate may be expressed from the smaller bronchi. The larger bronchi are injected and oedematous. The bronchial lymphnodes are enlarged and anthracotic. The branches of the pulmonary artery are normal.

Right Lung.—There are a few firm adhesions over the lower lobe laterally. There are a few old adhesions, lower portion of the upper lobe laterally. Some adhesion between the lower lobes by fresh exudate. The greater part of the lower lobe and the outer portion of the middle lobe are solid. The upper lobe crepitates throughout. On section the lower lobe presents a similar picture to that on the opposite side, but is perhaps of a deeper red color. The bronchi show the same velvety congested appearance. The lymph nodes are enlarged. The middle lobe is solid.

Heart.—The right auricle is dilated, otherwise the heart is normal.

Liver.—The liver is relatively normal in size and color.

Spleen.—The spleen is slightly enlarged. The capsule is smooth. The cut surface is mottled reddish-brown. The Malpighian bodies do not stand out prominently.

Kidneys.—Normal except for injection.

Adrenal.—The left adrenal is relatively normal in size. The cortex is paler than normal. The medulla is grayish-white and homogeneous. The right adrenal is somewhat larger than the left. Through the cortex are seen yellowish colored foci scattered throughout.

Bladder.—There is a slight injection of the mucosa.

Prostate.—The prostate is small. No gross change detected.

Rectum.—The rectum contains, in the lower portion, a few dilated hemorrhoidal veins.

Stomach and Duodenum.—Normal.

Aorta.—The aorta presents numerous small subintimal plaques extending down almost to the bifurcation.

Neck Organs.—The tongue, posterior to the circumvallate papillae, is very rough, injected and superficially oedematous. The pharyngeal mucous membrane is somewhat injected laterally, but not to any marked degree. The tonsils are small, normal in appearance. The pharyngeal injection extends down into the oesophagus as far as the hyoid bone. The epiglottis presents on its pharyngeal surface a few small hemorrhagic areas. The false vocal cords are oedematous. The true vocal cords are slightly oedematous. The upper part of the trachea is relatively normal. About 1 inch above the tracheal bifurcation it becomes more and more congested as you pass into the right and left bronchi.

Brain.—There is injection of the cortical vessels; moderate pial oedema. On section the choroid plexus of veins is distended with blood. On section of the cerebrum of mid-brain no abnormalities are noted.

Microscopical Notes:

Lung.—Section shows a uniformly solid appearance There is oedema, and the alveoli are filled with desquamated cells, large cells containing blood pigment and a

few degenerated red cells with a small number of polynuclears. The pleura is thick, congested and oedematous.

Another section shows a markedly thickened and oedematous pleura with a small amount of surface exudate.

Heart Muscle.—Negative.

Spleen.—The capsule in places is thickened. The Malpighian bodies are scanty, and those seen are very small. The central blood vessel presents a thickened wall. There is an excess of blood and blood pigment in the organ.

Kidney.—The kidney except for injection is normal.

Adrenal.—There is a noticeable oedema throughout the section. There are foci of degeneration of cortical cells.

Panereas.—The pancreas is normal.

Lymph Nodes.—Mesenteric lymph node normal. *Bronchial lymph node* shows a dilatation of sinuses which are rather sharply defined and contain large numbers of red blood cells and larger cells containing blood pigment.

Anatomical Diagnosis:

Lobar pneumonia—right and left.

Congestion of mucosa of pharynx, dorsum of tongue and esophagus.

Adhesive pleuritis—old.

Edema of larynx—slight.

Congestion of kidneys.

Summary of Post Mortem Appearances in Mustard Gas Poisoning: Respiratory Tract.—Inflammation of larynx, epiglottis, trachea and bronchial tubes, sometimes associated with ulceration and necrosis of the mucosa and the formation of casts. The bronchi often contain pus. The lungs show bronchitis, sometimes emphysema.

Alimentary Tract.—Pharynx and fauces present inflammation with or without a pseudomembrane or slough. The inflammatory reaction sometimes extends downward into the oesophagus, as in cases quoted above. Acute congestion of the stomach, with submucous hemorrhages occasionally present.

The *heart* is often dilated.

The *brain* shows simple congestion.

The *skin lesions* are superficial, blisters being the commonest type.

After Effects of Mustard Gas Poisoning.—The conjunctivitis, in the vast majority of cases, clears up fairly rapidly. In one or two weeks the eyes give very little trouble, and the patients begin to enjoy life once more. One man, observed recently, had a severe conjunctivitis with considerable inflammation and photophobia three weeks after being gassed.

The laryngitis cases vary considerably. Some clear up rapidly, others are obstinate. In one patient with superficial necrosis of the mucosa of the arytenoid cartilage there was no trace of the necrotic spot one week later, as already stated above, but he was still quite hoarse from his laryngitis.

We have not yet had an opportunity of examining the larynx, bronchi, and lungs of these men after the lapse of a fairly long period, say several months. However, it certainly seems reasonable to suppose that where there has been an intense chemical irritation and inflammation of the larynx and bronchial tree, in some cases, at least, more or less permanent symptoms will persist, such as dyspnea upon exertion, with cough and hoarseness.

Treatment—Prophylaxis.—Failure to carry the box respirator, and slowness and lack of practice in putting it on quickly, are responsible for many cases of gas poisoning. Then, too, it is self-evident that one should not wait to smell the gas before adjusting the mask, but should do so the moment the alarm is given, or a gas attack is suspected.

Adequate protection of the mouths of dugouts and a good system of gas alarms are highly important.

Immediate Treatment.—All severe cases of gas poisoning should be carried on stretchers and not allowed to walk to the dressing stations. As soon as the patient reaches a field hospital or casualty clearing station the clothing should be removed from the immediate vicinity of the patient and taken outdoors, where it is hung on ropes in the air for 2 or 3 days.

The patient himself should be put in a bath of sodium carbonate solution, or, if very sick, bathed on a rubber blanket.

If there is much respiratory distress, ammonia ampules and oxygen, followed by heart stimulants, are used. Venesection may occasionally be of value. The eyes should be bathed with 1 per cent. sodium bicarbonate, after which a bland liquid paraffin oil is dropped in and a bandage applied.

The new American hospital trains are fitted with oxygen tanks and electric fans to blow oxygen toward the patients.

Treatment at the Base Hospital.—The cases treated by us have had the following: Rest in bed. Soft or liquid diet. No smoking. (The patients do not care to smoke if their eyes are closed.) Bicarbonate of soda t.i.d. in thirty-grain doses. Eye bandage or eye-shade. Eye irrigations with 1 per cent. soda bicarbonate, followed by liquid albolene. After two or three days, substitute normal saline for the soda solution.

Cough is treated by the Robinson perforated zinc inhaler, on which is placed 3 or 4 drops of a solution containing equal parts of chloroform, alcohol, and creosote. Maw's steam inhaler, with compound tincture of benzoin, is used at regular intervals for laryngitis and bronchitis. Codeine is a useful drug in controlling the paroxysms of coughing.

Local treatment of the larynx and trachea was not tried during the acute stages. In one subacutely inflamed larynx, argyrol applications seemed to aggravate the subjective symptoms, and its use was abandoned.

The application of a bland mineral oil to the inflamed mucous membrane of the nose, pharynx, larynx, and bronchial tree seems to be the logical method of treating these cases.

This could probably best be accomplished by a compressed-air oil vaporizer, fitted with a mouth and nose piece, something like that of the Bennett ether inhaler. A portable apparatus of this type could be used by the ward nurse, and would not necessitate the personal services of the medical officer.

Facts About the Recent Epidemic.—Joltrain and Bayle refer specially to cases with high temperature and bronchopneumonia in which they obtained favorable results. They learned that these patients acquire a true immunity against further attacks. They employed many remedies—quinine, sparteine, strychnine, camphor oil in large dosage, intravenous injections of collargol and colloidal gold, antipneumococcus and antistreptococcus serum, etc.—*Le Progrès Médical.*

DEFORMITIES OF THE NOSE RESULTING FROM SYPHILIS: HOW SHALL WE TREAT THEM?

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK.

SYPHILITIC deformities of the nose are characteristic, and constitute a distinct class, the treatment and prognosis of which differ so widely from those of all other deformities that their separate consideration is necessary, whether from a clinical, pathological, or surgical point of view. The difficulties encountered, and the unsatisfactory results secured by the older methods, have to a large extent discouraged those who would help these unfortunates, who certainly merit our deepest sympathy and are entitled to our serious consideration; they have been neglected in the past, though there is much that can be done to relieve them.

From time to time I have received communications from my confrères asking for my opinion on the subject of syphilitic nasal deformities and their treatment, and it is in answer to these, and also through a desire on my part to direct attention to this difficult and neglected field of surgery, that I am prompted to make the following observations, which are based upon clinical experience: Owing to the pathology of the disease, the grave metabolic and nutritional disturbances, the amount of scar tissue usually present, the fact that bone and cartilage are the tissues chiefly involved in these cases, and the poor state of health in which these patients are generally found, syphilitic deformities of the nose cannot be corrected by the use of the bridge splint, by the transplantation of bone, by the shifting of tissue, or by the use of flaps, without first taking into consideration the etiology of the condition, combating the destructive influence of the disease which produced the deformity, and restoring as far as possible the general health of the patient. This should be done before any effort is made at surgical correction. Though I am fully aware that operative procedures may be undertaken involving the *soft parts* in other parts of the body without fear of untoward results due to the specific infection, yet I am convinced of the accuracy of my observations in regard to the nose by personal, clinical experience in more than one case, and I will say further that on several occasions in which specific infection had been denied, and was unsuspected by me, the postoperative behavior of the case suggested the etiology of the deformity, and this was subsequently confirmed by the Wassermann test and by the confession of the patient.

Bone transplantation in syphilitic subjects is distinctly contraindicated. Discussion of this subject is superfluous if we consider the pathological changes occurring in the bones in the tertiary stage of this disease, which changes are directly responsible for the deformity which we seek to correct.

While all bones in the body do not show grossly the same vulnerability to syphilitic invasion as the nasal bones, the septum, the bones of the skull, etc., yet we must remember that this vulnerability is strictly a local manifestation of minor resistance to the specific virus, which permeates all of the bones of the body alike. The removal for transplantation purposes, therefore, of a section of any bone in the body lowers its resistance and increases its liability to succumb to the specific invasion; and even if other considerations were favorable the chances of successful transplantation are markedly diminished. Other considerations, however, are not favorable, for in addition to the concentration of specific activity in the nose and its environs the remaining soft tissues of the nose are filled with a mass of connective tissue poorly supplied with blood vessels and hence of low vitality, having no reparative energy, and being utterly incapable of furnishing the requisite nourishment to transplant. The whole situation, therefore, is adverse to the successful transplantation of bone. The making of flaps is subject to the same unfavorable considerations. Flaps, especially those with pedicles, are extremely apt to die; for even if the ulceration has not extended to the skin surface the subcutaneous tissues are frequently so filled with this low-grade connective tissue that the blood supply to the skin is, in a large measure, cut off. To this is added an obliterative endarteritis always present in the third stage of this disease.

In closing a gap in the ala nasi I have, on more than one occasion, had the raw, approximated surfaces fall apart at the end of a week, showing that they possessed no more vitality or reparative energy than two pieces of leather. This experience, however, is not always met with, for if there is little or no scar tissue in the flap, if it is made thick enough, and is not stretched too tight, union will occur.

The prognosis, taking into consideration all of the factors involved, is not good for the correction of extensive deformities such as are usually found in tertiary syphilis so long as the patient is Wassermann positive, and even after we are reasonably certain that the disease is in abeyance we must be guarded in our opinion as to complete restoration of the symmetry of the organ by plastic means. Endarteritis is always present in tertiary syphilis, and this, especially in scar tissue areas, so restricts the circulation that in making flaps, primary union is secured only with difficulty, even if the tension is very moderate.

The difficulties here outlined apply to the nose and its environs, where a combination of diseased bone, cartilage, and scar tissue with the distinctive predilection of the specific virus for this area form a complex rendering successful bone transplantation and plastic measures almost impossible. These difficulties do not, as a rule, obtain in surgical procedures in other parts of the body, certainly not to the same extent as in the nose.

The preliminary treatment, therefore, of syphilitic deformities resolves itself into the problem ot eliminating, or at least getting under control, the specific disease and overcoming the nutritional derangements from which all of these patients suffer to a greater or lesser extent. So far as bone transplantation is concerned, it is useless to attempt it when the metabolic balance is badly disturbed and the patient's nutrition is far below normal.

In all syphilitic deformities I prefer to have the patient under my personal observation for at least two months before operation; during this time the medicinal, dietary, and hygienic conditions are carefully looked after. I can then usually judge whether

or not circumstances are favorable for operation. The degree of success depends chiefly upon the character of the deformity, the amount of tissue destroyed, the age of the patient, his constitutional state, and his nutritional condition.

In all of my specific cases there has been a considerable destruction of the soft parts and the framework of the nose. In all I have found it necessary to transplant bone and cartilage. In addition to this, in some cases I have had to shift the tissues or turn flaps. Where there was complete destruction of the nose I first transplanted the bone into the arm and then transferred the flap containing the bone to the face, thus making an entire new nose. These procedures, in the present state of our knowledge, constitute the only methods to which the unfortunate patient may look for relief. In the majority of cases we may assure him of a satisfactory correction provided that he submits to the necessary preliminary treatment, and provided that the operation is conducted by one skilled in plastic surgery and the art of transplanting bone; for these cases, in my opinion, require a full measure of patience, experience, and technical skill on the part of the operator.

69 West Fiftieth Street.

STUDY OF ETIOLOGICAL FACTORS BEARING ON THE THERAPEUTICS OF BELL'S FACIAL PALSY, BASED ON A REVIEW OF 177 CASES.*

By JOSHUA H. LEINER, M.D.,

NEW YORK.

ATTENDING NEUROLOGIST PHILANTHROPIN HOSPITAL; ASSISTANT ATTENDING NEUROLOGIST CENTRAL NEUROLOGICAL HOSPITAL, BLACKWELLS ISLAND; CHIEF OF CLINIC, NEUROLOGICAL DEPT. LEBANON HOSPITAL; CLINICAL ASSISTANT, NEUROLOGICAL DEPT., MT. SINAI HOSPITAL, O. P. D.

It is claimed by Steinart[1] of Leipsic that the seventh facial nerve is "more often than any other peripheral nerve affected alone." This fact can be fully corroborated when one refers to neurological clinical data and compares the affections of the peripheral nerves.

Because of its relative frequency and the drawbacks it often entails both from an esthetic and an economic viewpoint, any statistical inquiries that may throw some additional light should be reviewed.

Outside of the birth palsies due to instrumental compression (or otherwise) over the nerve at its exit, cervical adenitis, mumps, direct extension of middle-ear disease or caries of the petrous portion of the temporal bone, neoplasm or trauma, the major number are the so-called idiopathic type, due to exposure or rheumatism.

Every neurologist, in taking the histories of these patients, is given invariably the familiar and what seems a stereotyped history of sleeping near an open window, especially after taking a bath, and awaking with a paralyzed face; or sitting in a railway car, near an open window, or sitting in a draft. It has been found by some authorities[2] that about 72 per cent. of all peripheral facial palsies are due to the "catching cold or draft type."

The German claim that this type should be considered as rheumatic (and in fact they call it rheumatic palsy) is untenable. I have found few cases where there was a previous history of rheumatism or a rheumatic diathesis. Then again the consideration of this as a rheumatic neuritis is not borne out by its therapeutics. Clinicians know the absolute futility of administering the salicyl group for this condition.

Philip of Bonn (quoted by Dessert[2]) seems to have given us the most plausible etiological explanation, and that upon a neuroanatomical basis, *i.e.* a congenital narrowing of the stylomastoid foramina. Using this explanation as an hypothesis, the writer was led to a study of a series of skulls, to determine the terminal diameters of the exit of the Acqueductus Fallopii, *i.e.* the stylomastoid foramen. The skulls measured varied from individuals of recent demise to those of twenty years back. What was particularly striking in these measurements was the difference in the diameters of the two sides. Invariably the right side was narrower than the left.

Where the left side was one-eighth of an inch the right side was one-sixteenth of an inch. When the left side was as large at its exit as one-quarter inch the right side was one-eighth of an inch; or in a few instances the left side was one-sixteenth of an inch in diameter while the right stylomastoid foramen was apparently absent, or so small as to be measured in hairs' breadths only. This fact was more striking and illuminating in those skulls that were apparently of females. I say illuminating advisedly, as this bears out clinically that Bell's palsy occurs more often in the female than in the male (*vide infra*).

Through the courtesy of Dr. Joseph Byrne, I quote the figures I gathered at Fordham University. Of 33 skulls measured, 19 showed a smaller right-sided stylomastoid diameter, 9 showed the reverse, and in 5 skulls the measurements were equal on the two sides. The same proportion existed at Bellevue. One must understand that there is still periosteal tissue lining this area.

The next step in sequence would lead to a comparative clinical study; whether the above facts can be borne out and substantiated by clinical records.

A correlative study of the clinical records of the Mt. Sinai Hospital clinics of Drs. I. Abramson and H. Climenko (to whom I extend thanks), as well as of my own records at Lebanon Hospital, has led to very striking data.

One clinic showed 29 cases of Bell's palsy, of which 19 occurred on the right side, 7 on the left, and in three cases there was no record of the side. I take this opportunity to mention the fact that many clinics failed to state the side affected, being satisfied in simply making the diagnosis; this, however, makes it impossible to compile accurate statistics. One clinic showed this to the extent of 25 per cent. While the other clinics did not show the preponderating number of right-sided palsy, nevertheless the conclusion could be drawn that right-sided Bell's palsy occurs more often than that on the left side. This conclusively proves the original anatomical basis mentioned above.

That in view of the anatomical differences between the two sides there should occur a greater

*Read before the Bronx County Medical Society, December 18, 1918.

number of facial palsies than there are at present is obvious; this would be the natural deduction, but other factors enter, such as proportionate size of the nerve trunk, exposure, etc.

Bernhardt's statement that facial palsy is more common in the female is fully corroborated. The records before me show this in the proportion of two to one; furthermore, the anatomical basis is even more convincing.

Starr's view[1] that the season does not affect its frequency of occurrence cannot be concurred with. These cases were divided into two groups: (1) The so-called open-window season (April to September), and the closed-window period (October to March).

One of the series—31 cases—showed 21 cases as occurring between the months of April and September and 10 cases between October and March, inclusive. In another series of 139 cases, 79 occurred between April and September and 60 cases between October and March.

The anatomicopathological explanation is that as a result of exposure of a side of the face to the play of a current of air (draft), which leads to a rapid evaporation of the skin, with an accompanying superficial vasoconstriction and a simultaneous deep-seated congestion, the neurolemma of the nerve trunk becomes swollen and impinges upon the neuro-axial fibers because of the non-yielding bony constriction of the stylomastoid foramen.

That the resulting degeneration is of the parenchymatous, and not of the interstitial type, was shown by Markowski,[2] bearing out the above hypothesis.

Corresponding to the level of the involvement of the nerve, various neurological syndromes arise. This gives us a clue as to the intensity and distance that the nerve trunk is affected. As a general rule, I found (although there are exceptions) the more distal the nerve was involved the fairer the prognosis. In the series of cases I am not considering the seventh nerve involvement as it emerges from the pons, which is usually not a simple neuritis, but is a secondary involvement, due to a basilar meningitis, tumor, etc. The furthest level considered here is up to and including the geniculate ganglion. Involvement of the geniculate ganglion alone in an inflammatory process has been shown by Ramsey Hunt to manifest itself by an herpetic eruption in the external auditory canal and outer ear, just as involvement of any other ganglion would manifest itself. Many unexplainable pains in the ear, without any gross lesions being present in the membrana tympani or adjacent structures, have been shown to be neuralgic in character, due to geniculate involvement. Often this may be the first symptom in a facial palsy, as shown in some of the cases, when the inflammation extends to the nerve trunk outside of the ganglion. We therefore would have in Hunt's syndrome a facial palsy plus an eruption around the external ear.

If the inflammatory process extends to and includes the tympanic branch of the facial nerve which supplies the stapedius muscle, then the patient would complain of tinnitus aurium and hyperacusis. Usually, the patient will complain of this symptom without any inquiry.

As we descend in the Fallopian canal to about one-quarter of an inch above the stylomastoid foramen the chorda tympani branch is given off. When this is affected then there is a loss of taste in the anterior two-thirds of the tongue. The basic sensations of taste are lost. Although affection of the chorda tympani should lead to a dryness of the mouth (as it is the vasodilator of the submaxillary and sublingual glands), nevertheless I often found that there was not only an absence of this symptom, but in some cases an excessive salivary flow with a drooling from the mouth.

Treatment.—This detailed explanation was entered into so that the general practitioner who sees these cases early can appreciate what great benefit he can give his patient by immediate counter irritation in back of the lobe of the ear. Needless to state, cold should never be applied to relieve the congestion. Oppenheim tells of bringing on a Bell's palsy by applying ice to a patient of his who had tonsillitis.

Tincture of cantharides in flexible collodian is one of the best and most practical counter irritants. In Dr. Wm. Leszynsky's clinic this is used as a routine measure in these cases. Unquestionably, the ultimate prognosis could in many cases be favorably influenced by this simple measure, if seen early.

Involvement of the orbicularis palpabrarum prevents the eye from closing entirely, which is not only an annoying and troublesome symptom but may cause a drying of the cornea, conjunctivitis, etc. The eye should be bathed in a mild, warm antiseptic solution, and if inflamed a 10 per cent. argyrol solution should be used. At night I instruct the patient to use a piece of cotton dipped in a mild antiseptic solution, which should be applied to the eye and covered with a bandage. During the day he uses a black piece of cloth or kid leather attached to a string, to cover the eye. For very troublesome buccinator interference a metal hook can be placed under the upper lip, this in turn being attached to the cheek by means of adhesive plaster.

During the first ten days to two weeks no electricity should be given whatsoever. But about the end of this time a test should be made electrically to determine the amount of damage done. If faradic irritability is present in any degree, a more favorable prognosis is in store for the patient. I have seen these patients get better within two weeks.

If the muscles do not respond to faradism, and galvanism shows a reaction of degeneration, the prognosis should be guarded, and it often takes from three to six months to improve. For treatment, the make-and-break circuit should be applied to the motor points of the face at least three times a week. From one to six milliamperes should be used. If, after several months, a tonic contracture of the muscles sets in, then all electricity should be stopped. Warm packs should be applied and effleurage should be given to aid relaxation, if possible. A professional masseur would be the best adjuvant for this procedure. Balls placed beneath the cheek have been used, but I believe this helps very little to relieve this tonic contracture. Needless to state that the patient's general health should be looked after and improved whenever indicated.

If a case becomes chronic, that is, if after a year's treatment the condition is stationary, then the

patient should resort to surgery. The facial nerve is severed and the central end is joined to the peripheral end of the hypoglossal nerve. There is, of course, a coincident paralysis of the tongue on one side, but this leads to very little interference either in speaking or eating, in view of the interlacing and intertwining of the muscle bundles of the tongue.

Conclusions.—1. Bell's facial palsy occurs comparatively more often on the right side; this is shown both anatomically and clinically.

2. It occurs twice as many times in the female as in the male.

3. It occurs more often between the months of April and September, inclusive.

4. Because of the last mentioned fact the primary etiological cause is exposure, and this factor also enters in those cases occurring during the winter months.

5. Counter irritation should be the earliest, and proves the most efficacious remedy if the case is a primary facial palsy.

6. All electricity should be immediately stopped when the first symptoms of contracture appear.

7. Electricity (galvanism) is the only treatment in chronic cases, and should be employed even up to a year after the onset of the paralysis, providing there is no tonic contracture of the musculature. The writer has seen cases that have gotten better after a full year's treatment.

THE THERAPEUTIC VALUE OF THE SPAS AND HEALTH RESORTS OF AMERICA.

By H. H. ROBERTS, M.D.,
WHITE SULPHUR SPRINGS, W. VA.

Now that the great war has been brought to a sudden close, and the tension under which the American people have been for so many months will be relaxed, there exists not only a demand for spa treatment but a medical problem for the physicians of America.

Many thousands, in the years passed, have made their annual pilgrimage to the European spas and health resorts. All of these spas and health resorts were efficiently organized—managed by experts who understood the medicinal advantages of such treatment; and those who visited these European spas and health resorts know how actively and successfully they flourished. We know that their therapeutic value was based upon sound physiological principles, that their therapeutic efficacy was beyond dispute, and that their reputation was established to such a degree as was attested by many thousands who made their yearly visits.

All this has been changed. During the four years of the war the organizations were thoroughly demoralized; their doctors are scattered, the attendants killed, and in place of tourists their hotels are filled with the wounded and sick; and it will be many years before these spas and health resorts will be available for patronage again.

There are as many spas and health resorts in America that have beautiful environments, climatic advantages, and waters that are well known for their medicinal value. This has been verified by the Medical Department of the Army in the treatment of the wounded and sick as they return from Europe.

The use of water in the treatment of disease is not a new theory, but dates back to the days of Hippocrates, Plato, Homer, and Greek mythology. Even at that early date in the medical world the efficacy of water as a medicinal agent was recognized and used with great therapeutic value.

One unfortunate reason the spas and treatment resorts have not been a success in America is that the commercial idea has predominated, and that they have not been thoroughly and scientifically developed has been due almost entirely to lack of organization.

The success of the European spas and bathing resorts has been due to the system and organization and cooperation of the medical profession. It is not that they had waters more valuable than those in America or that their physicians were possessed of any greater degree of diagnostic skill or therapeutic knowledge, but the whole thing was system and organization.

We have mineral waters in this country just as valuable as the waters in Europe. The analyses show medicinal qualities equal to if not surpassing any of those in Europe. There are in America many springs in which radium emanations are equal if not superior to any of those in Europe. We have waters that are noted for their diuretic action; waters which have a sedative effect upon the nervous system. There are in America many spas and health resorts which are particularly beneficial in the treatment of neuroses and disorders of metabolism.

When the visitor arrived at one of the many European spas, he at once felt the effects of the environment. It was in the air; everybody was talking it; everybody felt it. The result was, the stranger entered into the taking of the "cure" with the greatest enthusiasm and the strictest obedience.

Possibly in no other commercial enterprise of today is there greater opportunity for the establishment of thoroughly up-to-date treatment and bathing institutions than at some of the well-known mineral water springs of America. The opportunity presents itself; the only requirements are experienced medical men, organization, and capital. If the physicians of America would give greater cooperation and encouragement to the development of the American spas, founded upon an ethical basis, success would be insured. Possibly there is no other country which furnishes a more wonderful variety of medicinal waters for drinking and bathing purposes than America.

By the use of water, hot and cold, cellular protoplasmic activity is materially increased—muscle cells, leucocytes, lymphocytes, etc. Cardiac contractions are made stronger, blood pressure may be raised or lowered, depending upon the primary excitant or the secondary depressant action of either hot or cold water. The primary effect and the sec-

ondary benefit will depend upon the temperature, the mode of application, and the duration, as well as upon the condition of the patient.

Blood pressure is raised after the application of cold water. The use of hot water lowers the blood pressure. The cutaneous blood vessels are capable of holding two-thirds of the amount of the blood of the body. This illustrates what a powerful influence is produced upon the blood pressure by any internal congestion, and which is so markedly relieved by the dilatation of the cutaneous circulation either locally or generally.

Respiration is increased by the use of a general hot bath, and as the bath is prolonged the respiration becomes deeper.

We can divert the blood from any congested part of the body with the application of intense moist heat to the surface of the skin. The circulation throughout the whole intestinal tract may be variously influenced by the use of hot and cold water alternately.

In the use of water for the treatment of various diseases of the body, we have an agent which possesses wonderful thermic flexibility. Because of its flexibility we can regulate its application with the greatest precision. In fact, there is no other medium which we now have that will admit of such a variety of applications as water. We can use it in many different forms, not only in its fluid state—hot and cold—but in the form of vapor, douches, sprays, etc., and we can change instantly from one to the other.

The beneficial effects are produced by the mechanical action of the water administered under various degrees of temperature and various degrees of pressure, which may vary from the mildest stimulation to the most intense irritation.

Water with its various gradations of temperature acts as a nerve stimulant, and by increasing or moderating the degree of temperature from high to low or low to high, affects the quality of innervation at the point of contact.

The peripheral sensory nerve terminations are increased or diminished or altered in excitability by the degree or mode of the application of water. This increase or modification depends upon the degree of temperature or force with which the water is applied to the body—the duration, the suddenness or slowness with which it is applied. The application may produce great good or great injury, its effects being exerted either at a local point or generally through reflex action. Marked benefits or injurious effects may result from the extraction or addition of heat to the body generally or locally.

Powerful beneficial action may be brought about by the proper excitation or stimulation of peripheral nerves. Metabolism of the body and digestion may be seriously depressed or greatly benefited by such stimulation. The frequency and force of the cardiac systole may be greatly influenced and local and general nutrition may also be markedly effected.

With the skilful use of water as a medium for therapeutic application we have an agent which affects different disorders of metabolism, or various secretions and excretions, all of which may be made to undergo many changes for good or for injury.

The reaction which occurs after any bath or thermal application will depend upon its intensity, and the curative effect almost entirely upon the reaction of the individual. There is a wide range of reaction after any bath and it varies greatly with the different individuals. The rapidity with which heat is restored after being extracted from the body varies immensely in different individuals. It is of the utmost importance that this be carefully controlled. An experienced physician will readily understand the necessity for the control of reaction in individual cases.

The greater the abstraction of heat the more intense the rise of temperature in the period of reaction. Therefore the duration, the degree of temperature, and the individual characteristics are all of the utmost importance in the use of hydrotherapy. The application of friction and other mechanical stimulation hastens the reaction. If the patient has taken active exercise before the bath the reaction is greatly increased.

The rapidity with which the cutaneous circulation responds to mechanical stimulation is an index to the reactive capacity of the individual. Therefore it is of the greatest importance that the patient be examined and carefully prescribed for by an experienced physician, and only thoroughly trained and experienced attendants should be permitted to give any form of treatment.

Disastrous results and the consequent disrepute of hydrotherapy have been brought about entirely by incompetent operators and pretenders. For this reason baths and other forms of water treatment should not be given as a routine, but should be carefully prescribed by experienced physicians for the individual cases.

Like many other therapeutic measures, hydrotherapy may be used for benefit or abused and great harm result. The apparently harmless medium—water—is a powerful factor for good or evil, and only those who are known to have experience and have been thoroughly trained should be permitted to use it. A thorough examination of the cardiac vascular system should be made before any bath is given.

In the use of water externally we have the various tub baths, varieties of sitz baths; many forms of douche—the Aix douche being one of the most important. The Vichy douche is a modification of the Aix. Compresses, fomentations, poultices, liver packs, wet packs, dry packs; all have their place in the therapeutic field. Nauheim baths are given with the various exercises and combinations of adjunct treatments as are adapted to different conditions.

Medicated baths, pine, rose, lavender, thyme, mustard, and a great variety of perfumed baths for many therapeutic indications of skin and general effects may be used. Mud baths, peat baths, fango baths, bran and meal baths, hot sand baths, etc.; light rays, chemical rays and other electrical effects producing chemical effects and radiant heat upon the body are available.

Electrothermic generators, electric light cabinets with various combinations, steam cabinets, phototherapy, open air sun baths or heliotherapy, scientific tanning of the body, together with many forms of electric treatments, static, sinusoidal currents, galvanic and faradic currents, high-frequency treatments have wonderful therapeutic value. These

baths and treatments should never be administered except under the authority and direction of qualified and licensed physicians.

The application of hot water to the body causes increased elimination of CO_2, and also increases intermuscular oxidation. The local application of heat by hot water, mud, or electricity, produces a local leucocytosis. The color index is raised, leucocytosis and erythrocytosis are increased by the use of cold applications of water to the body. However, it is important that a good reaction be secured, otherwise this result is not produced but the reverse may result.

Hot mud baths, fomentations, poultices, diathermy by electric application all cause a local increase of the leucocytes and diminution in red cells. A warm sitz bath produces reduction in both white and red cells.

Cold water applied to the cardiac region quickens the heart beat and later produces a slow but stronger beat. Hot water produces the reverse effect.

By sipping very hot water, the secretions and peristaltic action of the intestines are increased. The use of warm water, however, will cause the reverse effect. The sipping of very hot water at intervals has a very powerful reflex effect upon organs and glands adjacent to the stomach, such as the gall-bladder and pancreas. The application of intense heat over the gall-bladder, stomach, spleen, etc., increases secretion and motor activity as well as stimulating the circulation in these organs. The general application of heat relieves acute inflammation of the kidneys. If the bath is given short of perspiration the flow of urine is promoted and general renal activity is increased.

The uses to which we may apply water as a medicinal agent are almost innumerable. Many diseases of the gastrointestinal tract, of the pelvic viscera, and of the kidneys, the uric acid diathesis, diabetes, both acute and chronic rheumatism, bronchial catarrhs, acute and chronic congestion of the liver, and all conditions of either local or general congestion and faulty metabolism are benefited or cured by hydrotherapy.

The internal administration of water is equally as important as the external, and the therapeutic value depends upon the temperature, the quantity, and the time of administering.

Water is taken up by the tissues of the body with greater or lesser rapidity. If some normal or pathological condition has produced a profuse perspiration, diarrhea, diuresis, bleeding or any unusual loss of fluid from the body, the more rapidly will water introduced into the body be absorbed by the blood-vessels.

As water comes in direct contact with the digestive canal it has a most important influence upon the nutritive process, on account of its chemical effect and the equalization of the body temperature.

Drinking very cold water reduces the pulse beat, and the temperature of the body will also decline with the pulse beat, but within a few moments will return to the normal.

Cold water reduces the temperature of the stomach and the normal temperature is not regained for several hours. For this reason ice cream and iced drinks are most injurious when taken with meals or at the end of a meal, digestion being retarded for a considerable period.

The lower the blood pressure at the time of drinking water the more rapidly will it be absorbed. Water containing a small portion of saline matter is more readily absorbed. Carbonated waters are rapidly absorbed. Within one hour after water has been taken into the stomach it appears within the tissues and within three hours has been eliminated from the system.

We know that there are spas and treatment resorts in America in which the circulatory and cardiac conditions are treated with just as much success as at any of the special spas of Europe. The Nauheim baths given in America are equal to if not superior to any of those given in Europe. For the treatment of all chronic constitutional diseases, such as rheumatism, anemia, functional nervous diseases, digestive conditions, faulty metabolism, etc., there are none superior.

The field of natural therapy is unlimited in the good to be secured. This has been demonstrated by many years of faithful work of honest and conscientious medical men.

The opportunity is now. Will the American professional and business men allow this opportunity to pass, or shall we have a system of scientifically and ethically conducted spas and health resorts in America which will surpass those of any country in the world?

THE GREENBRIER.

A CASE OF ACUTE MASTOIDITIS WITH PERISINUS ABSCESS, FOLLOWING INFLUENZA PNEUMONIA; OPERATION PERFORMED UNDER NOVOCAINE AND MORPHINE ANESTHESIA.

BY JOSEPH EASTMAN SHEEHAN, M.D.,

NEW YORK,

INSTRUCTOR IN DISEASES OF NOSE AND THROAT IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING EAR SURGEON ST. MARY'S HOSPITAL, ORANGE, N. J.; CONSULTING EAR SURGEON, PORT JERVIS HOSPITAL, PORT JERVIS, N. Y.

THE following case presents some interesting features.

Eight days after an attack of influenza, which ran a severe course, I was called to see Edward P., age 9½ years, Jersey City, in consultation with Dr. Henry Woelfle. The boy complained of severe frontal headache with pain in both ears and was moaning. His pulse was 132 per minute, respiration 48, temperature 104° F. He had a rough, harrassing cough which was non-productive. Dr. Woelfle stated that pneumonia was present with few signs in his lungs. I quite agreed with him. A few râles were only discernible at the right inferior scapular region.

The examination of the right ear showed the tympanic membrane very congested, the head of the malleolus only could be seen. There was no bulging. Examination of the left ear showed a congestion along the course of the malleolus and of Shrapnell's membrane. Examination of the nose showed the turbinates markedly congested and of an angry purplish red hue. The mucous membrane of the septum was also congested. The throat revealed nothing of special interest except some redness along the lateral wall of the pharynx. The larynx was normal.

A 10 per cent. solution of ichthyol in glycerin was ordered to be dropped into both ears twice daily. An oily spray consisting of camphor and menthol was ordered sprayed into both nostrils four times daily. The

pain quite subsided in the course of a few days and the boy complained of no further trouble in his ears.

Nine days after my first visit I was again called to see the patient. Examination of the right ear showed the tympanic membrane of normal appearance. The membrane of the left ear showed marked bulging and was of a red gray hue. The turbinates were still congested. The throat was normal. There was extreme tenderness over the mastoid antrum, emissary vein, and to a lesser degree over the tip. Incision of the membrane was performed and a large amount of sanguino-purulent discharge exuded. The pain and tenderness quite subsided for two days.

Five days after the incision of the drum, I saw the case again. The boy was extremely ill, temperature 104°, pulse 140, respirations 40 per minute. There was a profuse purulent discharge from his left ear. The tenderness over the antrum and emissary vein was very much less than at the time of incision of the drum. Deep pressure over the tip elicited only a fair amount of pain. An operative mastoiditis presented itself. Ether and chloroform were out of the question as he was very toxic from his pneumonia. After consultation with Dr. Woelfle, I decided to perform the mastoid operation under a local anesthetic, in the house.

Operation.—One-half hour previous to the operation a hypodermic of morphine, 0.006, was given. A solution of 1 per cent. of novocaine was injected into the skin along the line of the proposed incision, going well into the surrounding tissues toward the lobe of the ear, the zygoma, occipital bone and downward below the tip. The regular circular incision was made throughout its whole length down to the periosteum, eight cubic centimeters of the solution being used. An injection to the amount of three cubic centimeters was made under the periosteum, reaching well down below the tip, forward toward the ear, posteriorly toward the occipital bone and upward toward the zygoma. The area injected was about two inches square.

The periosteum was incised, great care being taken not to lacerate it, as so doing would prolong the repair of the wound. It was then scraped backward and forward. Dull retractors were used to minimize pain. As we proceeded painful areas were injected, but this was not frequently necessary.

After the bone was exposed, the mastoid cavity was opened with a chisel. Up to this time the patient complained of very little pain; in fact, he was talking and whistling, quite to the amusement of all present. The cells at the tip were particularly large and filled with granulations and pus. The antrum was exposed and found to contain much pus and granulations, which were thoroughly curetted and cleaned. The additus was exposed and carefully curetted of thick granulations. This was the first time the patient complained of pain. An injection was made into the sensitive granulations and the operation proceeded uninterruptedly.

After exposing the bone a little below the region of the emissary vein, a perisinus abscess was noted. The bone was very necrotic, which necessitated the removal of a considerable part of the bony plate covering the lateral sinus, leaving a wide area of the sinus exposed. There were granulations on its outer side, with some ulceration.

After removing all overhanging ledges of bone from the margins of the bony wound, I again inspected the additus and made sure that all granulations were removed from its roof and floor.

Great care should be exercised in removing granulations from the floor of the additus as quite frequently they are attached to the short process and body of the incus; particularly is this true in chlidren.

The wound was flushed with sterile saline solution, mopped dry, and packed not too tightly with iodoform gauze, care being taken that the gauze pressed into every portion of the bony cavity.

Silk sutures were carried through the entire thickness of each flap so that there would be a better skin approximation, and particularly of the periosteal edges. A gauze wick was inserted into the auditory canal. The external wound was covered with the usual dressing.

The wound was dressed daily after 48 hours for ten days, the gauze strip being removed each time and a shorter piece reinserted. As the discharge lessened and the drum assumed a more normal appearance, dressing the wound every second day was quite sufficient.

The patient ran a protracted course of pneumonia. Three weeks after the operation, the wound closed. Examination of the patient at the time of this writing shows him in a very healthy state.

Conclusion.—1. The mastoid operation can be performed with entire satisfaction under local anesthesia, provided the skin, periosteum, additus, and membrane of the middle ear are properly anesthetized.

2. The bone has no sensation.

3. Injury to the facial nerve is immediately noticed.

4. There is practically no after-effect.

5. Local anesthesia should be employed in all cases where the administration of ether or chloroform would be an added danger.

24 East Forty-eighth Street.

THE TREATMENT OF SCABIES IN PRIVATE PRACTICE.

By CHARLES GREENE CUMSTON, M.D.,

GENEVA, SWITZERLAND.

PRIVAT-DOCENT AT THE UNIVERSITY OF GENEVA.

THE prevalence of scabies since the war, even among the well-to-do, is the only excuse for this short note on treatment. What both patient and physician desire is a rapid, effective, and uncomplicated procedure for eliminating the busy little parasite in the skin.

Up to within a short time the treatment of scabies was complicated, very uncomfortable, and rather long, in that several days were occupied in treatment. Quite recently Oppenheim (*Wiener medizinische Wochenschrift*, Nov. 15, 1918) has published what he calls a rapid cure for scabies, based on the treatment of twelve hundred cases. It is carried out as follows:

The entire body is rubbed for a quarter of an hour with sapo viridis, after which the patient enters a warm bath and removes the soap with a brush or wood-fiber. The process of mechanical removal of the soap should last one-half hour.

The patient then comes out of the bath and dries the skin thoroughly with towels, after which the following is applied:

℞

Sulphur. praecip.	25 gram.
Potass. carbonat.	10 gram.
Vaselini	125 gram.

M., ft. unguentum.

Two hours later another warm bath is taken, the ointment is washed off, and, after drying the skin, a zinc paste is applied. This completes the cure.

I have had no experience with the above rapid cure of scabies, but as Oppenheim has resorted to it in twelve hundred cases with apparent success (since he does not refer to failures) it seemed well worth recording.

I have, however, obtained remarkable results in private practice with the following treatment, due to my friend, Prof. Charles Du Bois of Geneva. There is little cutaneous irritation following it and a cure can be obtained within a single night if the

procedure is carefully and exactly carried out.

The patient rubs sapo viridis carefully all over the body and neck up to the chin, care being taken to cover well the interdigital spaces of the hands and feet.

A hot bath of one-half hour's duration is then taken, the soap being removed by *mild friction*. After the skin has been thoroughly dried, the following ointment is rubbed in:

℞

Ichthyol,	10 grams.
Pommade d'Helmerich,*	80 grams.
Camphor. trit.,	2 grams.

M., ft. unguentum.

The patient dons some old underwear and retires for the night, although I would add that the ointment does not stain the clothes.

On the following morning a hot bath, to which 100 grams of hepar sulphuris have been added, is taken, the patient remaining in the water for a quarter of an hour, after which he simply dries himself with towels. This completes the cure.

As the hepar sulphuris requires some time to dissolve, the patient should be instructed to place the 100 grams of this drug, to be used in the morning bath, in a two-quart pitcher of hot water and allow it to remain over night. In the morning it will have dissolved and can be poured into the bath.

In order to render the ichthyol-sulphur ointment more readily accessible to American practitioners, I would suggest the following formula:

℞

Ichthyol,	10 grams.
Sulphur, sublimat.,	12 grams.
Potass. carbonat.,	6 grams.
Camphor. trit.,	2 grams.
Adipis,	60 grams.

M., ft. unguentum.

Precipitated sulphur being somewhat more active than sublimated sulphur, the former may be preferred by some. Its greater activity is due to its extremely fine division and also that it gives off a certain amount of sulphureted hydrogen.

No mention of change of clothing, bed-linen, etc., has been made, as it is assumed that the absolute necessity for so doing is well known to all.

In conclusion it may be said that the treatment outlined can be satisfactorily carried out in any private house, and I am aware of no other method which cures as rapidly without any undue cutaneous inflammatory reaction following, even in those with delicate skins.

3, Rue Bellot.

*The pommade d'Helmerich of the French Codex is composed as follows:

Sulphur. sublimat.		10 grams.
Potass. carbonat.		
Aquae	āā	5 grams.
Ol. papaveris adipis		35 grams.

Fatal Pulmonary Congestion in Influenza.—Tremollières and Durand relate the case of a patient with influenza who succumbed rapidly amid signs of massive congestion of the lungs. Autopsy revealed the following state of affairs: intense areas of congestion simulating infarcts, areas of catarrhal pneumonia and of suppuration, numerous pathogenic microorganisms. Apparently no clinical evidences of pneumonia had developed.—*La Presse Médicale.*

Medicolegal Notes.

Expert Testimony as to Future Physical Condition.—In an action for personal injuries to a brakeman by a fall while boarding a freight car at night, when his leg struck against a keg of spikes on the right of way, it was urged for the defendant that error was committed in the admission of the testimony of one of the physicians introduced by the plaintiff. This inquiry was propounded to him: "Doctor, supposing that the condition you found was the result of an injury which happened on the sixth day of October, 1913, have you a judgment as to whether or not that condition will be progressive?"

After the interposition of a general objection by counsel for the defendant, which would not authorize a review of this contention unless the inquiry was wholly inadmissible, the witness answered: "I think it highly probable that the trouble will progress, in view of what I have seen and the length of time he was hurt."

The further question was asked the witness, "And, if progressive, what would be the result?" to which he replied, "He will be rendered helpless." The objection to this testimony was that it permitted the witness to express his judgment on a probability or to base an opinion upon an opinion. The court said that the hypothesis upon which the inquiry was made was based, not upon an opinion, but an established fact, viz., that the plaintiff had struck the keg in attempting to mount the car, and had thereby sustained the injuries which had been found by the witness upon a personal examination, as a physician, to exist. At best, testimony of this character is advisory and not conclusive. Cognizable of this fact, the trial court gave the jury the usual instruction as to the weight to be given to the testimony of witnesses of this class. They were told, among other things, in the stereotyped language usually employed in this instruction: "That the opinions of expert witnesses neither establish nor tend to establish the truth of the facts upon which they are based." Thus guided and otherwise fully instructed as to their province as judges of the weight and credibility of all the witnesses who had testified, the possibility of their being prejudiced or influenced one way or the other in reaching their verdict by the testimony of this witness was held exceedingly remote, if it existed at all.—Laughlin v. Kansas City Southern R. Co., Missouri Supreme Court, 205 S. W. 3.

Recovery Under Physician's Indemnity Policy.—A physician's policy of indemnity insured him against loss from liability for damages on account of bodily injuries or death suffered by any person or persons in consequence of any malpractice, error or mistake of the plaintiff as a physician, or from any suit against him to enforce any such claim whether it was groundless or not, and the insurance company agreed in the policy to defend any such suit. Suit was brought against the physician, charging him with malpractice in treatment both prior to and after the issuance of the policy. The insurance company refused to defend the suit, as a consequence of which the physician defended it, and settled the claim. It appeared that the physician's treatment of the patient was commenced some time before and continued several weeks after the company issued to him the policy. In a suit on the policy it was held that the company should be required to reimburse the physician for the amount paid by him on account of the patient's suit.

An instruction told the jury that where a physician has an undischarged case at the time of the issuance of a policy of insurance, such as the plaintiff's, and the patient should continue under the physician's care after the policy was issued, this would constitute a continued liability. This was held to be erroneous. There certainly would be no liability under the policy, except for malpractice committed after the date it was issued, and it would make no difference how long the patient continued under the doctor's care, unless it was claimed that malpractice had occurred after the policy was issued. But as it was expressly stated by the insurance company that the plaintiff was guilty of no malpractice, and that the sum paid by him was reasonable, the judgment would not be reversed by erroneous instructions, as there was no defense to the plaintiff's claim. Judgment for the plaintiff was therefore affirmed.—Waterman v. Fidelity, etc., Co., 209 Ill. Appl. 284.

Military Medicine.

Demobilization and Venereal Disease.—A special conference was held at the Royal Institute of Public Health in London on January 8 (*Lancet*, January 18, 1918) to discuss the question of venereal diseases and how best to control them. At this conference there were present English, American, Australian and Canadian medical men. The discussion was opened by Col. J. G. Adami, C.A.M.C., who after somewhat severely criticising the apathy of the Government of Great Britain with regard to the venereal problem proceeded to advocate that before demobilization the soldier should be provided with the means of prophylactic treatment, should be advised where and how to obtain "tubes" without difficulty, and, moreover, be given precise detailed instructions as to the method of employment. For the good of the country he saw no other possible course. Col. Hugh H. Young, M.C., U.S.A., strongly recommended the use of prophylactic treatment which was enforced in the United States Army in 1912, and in the following five years venereal disease was reduced nearly 50 per cent. Lieut.-Col. Sir James W. Barrett, R.A.M.C., in giving the experiences with the Australian troops, said that moral force had been brought to bear, but it was only after the use of prophylactic methods that any general good had resulted.

The sentiment of the meeting was first that the situation with regard to venereal diseases in Great Britain was very serious and due to become more serious when demobilization was in full swing, and secondly that the only measure which appeared to be likely to control the spread was the adoption of what may be termed direct prophylactic methods. Evidence seems to show that such means, when rigidly enforced, is effective in diminishing the spread of venereal infection as was notably shown among the soldiers of the British army in Egypt. There is a great deal of antagonism against the introduction of direct prophylactic measures into Great Britain, based almost entirely on so-called moral grounds. The argument of those who advocate these methods is that such sentiments must not be allowed to imperil the health of a nation. Unless drastic steps are taken during the next few months venereal diseases are certain to spread and as prophylactic measures have proved to be effective in armies, including the American regular army, the Italian army, and the Australian army, there is reason to anticipate satisfactory results from their employment in civil life. It is a matter which requires very delicate handling, but there should be found a way to employ prophylactic measures in civil life which will meet the situation and not too greatly conflict with religious or moral scruples.

Dr. Ralph G. Stillman has returned from service overseas in the medical corps and has resumed practice at 27 East 62d Street.

Dr. Louis J. Ladin has received his discharge from the army and has resumed practice at 1289 Madison Avenue. Dr. Ladin has by permission of the Court taken this name in place of Ladinski, by which he was formerly known.

Dr. Livingston Farrand, president of the University of Colorado, has been appointed chairman of the Central Committee of the American Red Cross, to succeed William H. Taft, and will become the executive head of the National Red Cross organization on the retirement of the War Council, which will take place March 1. Since the entrance of the United States into the war, Dr. Farrand has been the director of the tuberculosis work of the International Health Board in France.

German Medical Practice Restricted.—Evidence of American determination to prevent fraternization between Germans and men of the United States army of occupation was given recently at Coblenz in the issuance of orders forbidding American soldiers to consult German doctors.

Reconstruction Work Facilitated by the Red Cross.—The American Red Cross has placed at the disposal of the Army Medical Corps for use in reconstruction work, an emergency fund of $200 per month for each base and general hospital engaged in this work. There are forty-four hospitals engaged in such activities and the gift will mean an expenditure of nearly $10,000 a month by the Red Cross alone in the work of re-educating disabled soldiers. The money is not to be used for the purchase of supplies, equipment, and service, which must be provided from army supplies or funds.

Psychiatrical Tests for all Recruits.—The recommendations formulated at a recent conference of a corps of psychiatrists of the Medical Corps of the Army have been approved by Secretary Baker. The conference recommended the establishment of a corps of psychiatrists of the Medical Department for duty at recruiting depots to weed out applicants for enlistment who might be adjudged incapable of conforming to army discipline. A second step urged by the conference is the erection of development detachments into which men adjudged as doubtful might be received for study to determine whether they should be passed into the army. Men serving prison sentences would be sent to the development detachments of recommendation of the commandant of the prison. Vocational education at the prisons was also featured in this report, which urges that men dropped from the rolls as deserters after an absence of three months, but who surrender voluntarily, be sent to the disciplinary barracks for trial so that an adequate study of their mental condition may be a factor in determining punishment. A system of correspondence courses for prisoners is also recommended and commandants are authorized to recommend earlier parole for men who complete such courses.

Discharged Tuberculous Soldiers.—Since the beginning of the war twenty-four thousand soldiers have been discharged from the army as tuberculous. Recently Dr. W. G. Stimson of the United States Public Health Service appeared before the Senate Building Committee in order to urge the Government to make more liberal provision for the care of these men.

Army Surgeons for Siberia.—The War Department has issued orders assigning fifty-two medical officers for duty with the American Forces in Siberia. The party, including seven majors,

nineteen captains, and twenty-seven lieutenants, will sail from San Francisco. These officers are to relieve a similar number of medical officers who have been in service and have indicated their desire to return to civil life. Under the policy of the War Department medical officers asking for discharge will be replaced as far as possible by men who have applied for retention in the permanent establishment.

Many Wounded Soldiers Studying.—Of the wounded soldiers in hospitals in the United States, 12,249 registered in December for various educational or other courses of instruction provided by the military authorities. According to a statement issued by the Surgeon General, 2,010 men applied for shop and trade courses, 1,117 for courses in commercial subjects, 564 for agricultural, and 1,633 for recreational courses. The others chose scattering courses. Such courses are now being given in twenty-three army hospitals.

No Let-Up in Red Cross Work.—A statement issued by Henry P. Davison at the Red Cross Headquarters in Washington, under date of February 12, announces that the efforts of the American Red Cross are to go on without abatement in all parts of the world in which activities are being conducted, and that the transition of the organization from a war to a peace basis will follow the line of continued effort rather than a restriction of endeavors. The War Council, however, will pass out of existence on February 28. It is said that Mr. Davison and several other members of the War Council will remain on the executive committee.

Navy Recruiting Office Calls for Hospital Corps.—Lieut. Com. D. P. Wickersham, in calling for recruits, states that special schools have been established for the instruction of men who enlist in this branch of the service. These schools will provide courses in elementary anatomy, first aid and emergency surgery, pharmacy, chemistry, and compounding of medicines, hygiene, care of the sick, and surgical procedures. Those who show special ability may avail themselves of courses in bacteriology and other laboratory examinations and tests, and the *x*-ray. The recruiting office for the New York District is at 34 East 23rd Street.

Grave Accusation Confronts German Doctors.—According to a recent despatch to the *New York Sun*, the suspicion is widely prevalent in British hospitals and among British soldiers returning from German prison camps that the German doctors deliberately inoculated English soldiers with tuberculosis. The British War Office is going to make an official investigation into these charges. It is reported on reliable authority that the number of British soldiers returning from Germany with tuberculosis is appalling. Dr. Theodore C. Beebe, in charge of the American Ambulance Hospital at Neuilly, France, is quoted as stating that although he could not obtain indubitable proof, the evidence tends to confirm the belief the Germans made deliberate attempts to spread tuberculosis throughout France. The feeling is growing among physicians in this country that if charges of this kind, so contrary to the traditions and principles of the medical profession are proven the resumption of fraternal relations with the medical profession of Germany will be absolutely out of the question for many years to come.

Deaths in the Service.—Capt. Howard Emerson Ames, U. S. Navy (retired), of Washington, D. C., died in the United States Naval Hospital, Washington, D.C., December 27, aged 68 years. He was a graduate of the University of Maryland, Baltimore, in 1874, a member of the Greeley Relief Expedition, one of the first sent to Kingston, Jamaica at the time of the earthquake, and was in command of the Chelsea Hospital at the time of the great fire in Boston. He was a member of the Association of Military Surgeons of the United States. His last assignment was at San Francisco, where he was retired on August 7, 1912.

Lieut. Carl Adolph Breitling, M. C., U. S. Army, of Brooklyn, a graduate of the Northwestern University Medical School in 1913, on duty at Camp Greenleaf, Ga., died of bronchopneumonia at Fort Oglethorpe, Ga., on November 5, aged 32.

Lieut. Frederick Wilkinson Olcott, P. A. Surg., U. S. Navy (retired), Washington, D. C., a graduate of the College of Physicians and Surgeons, New York City, in 1884, died at the Government Hospital for the Insane on January 26, aged 57 years.

Capt. Washington Berry Grove, U. S. Navy, a graduate of the University of Virginia, Charlottesville, in 1896, who was in command of the Norfolk Hospital, Va., as executive surgeon from October, 1915, to December, 1918, and who was recently assigned to the command of the U. S. Naval Hospital at Washington, D. C., died in that institution on January 21, aged 43 years.

Capt. Elmer Ellsworth Holt, M. C., U. S. Army, of Mena, Ark., a graduate of Barnes Medical College, St. Louis, in 1898, honorably discharged from duty at Camp Jackson, Columbia, S. C., in December, 1918, died at his home, January 23, from a gunshot wound believed to have been self-inflicted, with suicidal intent, while suffering from mental derangement following influenza, on January 23, aged 51 years.

Lieut. Paul Carroll Dennett, M. C., U. S. Army, of Boston, a graduate of Tufts Medical School, Boston, in 1916, on duty with the Seventy-fifth Coast Artillery Company, American Expeditionary Forces in France, died from influenza in Base Hospital No. 65, near Brest, on October 16, aged 26 years.

Capt. William Frank Guilfoyle, M. C., U. S. Army, of Philadelphia, a graduate of the University of Pennsylvania, in 1905, on duty with the American Expeditionary Forces, and assgined to the Eleventh Infantry, Twenty-eighth Division, was gassed several times, and died in Base Hospital 31, on September 2, 1918, from exhaustion, aged 36 years.

Lieut. Edward Francis Phelan, M. C., U. S. Army, of North Brookfield, Mass., a graduate of the University of Vermont, Burlington, in 1909, aged 32 years, on duty with the British Army overseas, is reported to have died recently.

Dr. Leonard M. Kalaher, M. C., U. S. A., of Jersey City, died February 5, at Base Hospital 78, Toule, France, where he was serving as a surgeon. He was 28 years old.

THE ETIOLOGY OF RUPTURE OF THE VALVES OF THE HEART.

THE relative frequency of valvular rupture is a well established fact, the best of recent statistics being due to Rannellitti who has collected seventy-nine cases, namely, forty-nine ruptures of the aortic valves, twenty-seven of the mitral, two of the tricuspid, and one of the pulmonary. These figures show that ruptures of the sigmoids of the aorta are about twice as frequent as those of the mitrals, although the former were not recognized until a later date. As might be supposed the ratio of rupture is five cases in the female to ninety-five in the male.

Two etiological factors are in themselves sufficient to produce rupture, namely, an effort or direct trauma of the thorax. The latter is usually a sudden and violent blow over the precordial region, while occasionally the trauma is combined with a fall. No less important for the production of valve rupture is the part played by an effort, but on this point there is still much discussion. Some writers, Barié in particular, makes a distinction between traumatic ruptures and those resulting from an effort, which he terms spontaneous rupture. From the viewpoint of etiology this distinction is excellent and puts order in the much confused question, but its value must not be exaggerated. Ostwald has well seen the principal objection to this distinction when he points out that a muscular rupture is traumatic when it follows a spontaneous sudden movement without the help of any external cause and there is no reason why a valve which has regularly carried out its functions and ruptures after an effort on the patient's part should not be regarded as traumatically ruptured. These remarkes are exact and it is clear that in valve rupture from an effort, trauma is quite as important a factor in the process as it is in the case of certain hernia. In the present state of our knowledge, it would appear logical to admit three types of valve rupture, because there are cases in which both trauma and effort are combined, namely, (1) rupture from direct trauma over the thorax; (2) effort ruptures which result from a single sudden strain, and less frequently, repeated strain, such as bicycle riding; (3) ruptures produced by direct trauma and violent effort combined.

As to the relative frequency of the two etiological factors, Stern's statistics, as well as those published by Rannellitti, show that strain is the more important. The latter writer found that strain alone was the causative factor in forty-three cases out of a total of seventy-nine, the remaining thirty-six being the result of a direct trauma. The two factors just considered are in themselves capable of producing rupture without the aid of any local or general predisposition. Both unquestionable clinical facts and necropsy findings have proved this. On the other hand, some predisposition related to some pathological conditions of the valves on the entire cardiovascular system existed in a very large number of cases. These consisted of changes in the endocardium of the valves due to former rheumatism or some infectious process, likewise arteriosclerotic or syphilitic lesions of the aortic orifice, and finally hypertension which is also a predisposing factor of the first order.

When some predisposing factor is present a very slight trauma is all that is required to produce rupture and from the clinical viewpoint this fact alone is enough to cause one to suspect the predisposition. This is an important sign in medicolegal cases, because the preexisting lesion may have remained clinically latent up to the time of the receipt of the trauma or the subject may, from personal interest, have voluntarily dissimulated the morbid phenomena to which he had been previously subject. The proof of these predisposing factors has been furnished by numerous autopsies, but the pathological findings are only of value when death occurs precociously. If the proof is made only after a certain lapse of time following the receipt of the trauma it may be questioned whether or not the lesions are secondary to the injury.

PROHIBITION AND AFTER.

WHETHER country-wide prohibition goes into effect in July or not, the reign of John Barleycorn will definitely cease next January, and speculation at this time as to the results on the health and habits of the people is therefore not premature. If we may reason from what has happened in those States where real prohibition, and not merely a change of status from stabile to mobile of the saloon, has existed for several years, it is safe to predict an increase in drug addiction with the exit of alcohol. Not that all alcoholics will become "coke" fiends or heroin addicts, for some will die or go daft and many others will gradually lose their longing and recover normal health, but a fair proportion of those now seeking surcease of care and worry in alcohol will be driven to find it in opium or coca derivatives. Others will get the necessary stimulation from caffeine, and the consumption of coffee and tea will doubtless increase, with perhaps the addition of maté and similar little known South American "yarbs."

Then there will be the multitude of "soft" drinks

—the near beer, the unfermented juice of the grape, of the apple, the pineapple, the loganberry, the orange, and some other fruits now little known or cultivated. These fruit juices, still or sparkling, but unfermented, will largely take the place of wine, when the present dwindling private stocks of the latter are exhausted, and for the majority of moderate drinkers, who seldom take enough to "feel" it, they will answer in fair measure the esthetic and sociable requirements of wine. Already some of the brewers whose manufacture of beer ceased two or three months ago, are preparing to make the best of the inevitable and to turn out presentable imitations of beer and especially of wine. The problem of the latter is of course the preservation. Chemical preservatives will not meet with favor, for the "near wine" drinker will dislike the label stating that this package contains such or such per cent. of this or that antiseptic or germicide, and he will be afraid of the possible effects of the drug on "the coats of the stomach"—though he never had any such fear of the 20 to 40 per cent. of alcohol. Pasteurization will be available in the case of certain beverages that are to be consumed within a short time or that are kept in sealed containers, but for the ordinay "bottled goods" without the sting, some other method of preservation will be found desirable. Necessity is the mother of invention, and already certain processes have been devised which promise to meet all requirements, and are even now being employed in the preparation of palatable beverages for the anticipated wants of the drinking public.

The effect prohibition will have on the health of the community will vary according to circumstances. The alcoholics who switch off to drugs will be bettered or made worse according to the degree of the previous abuse of alcohol and that of the present abuse of drugs, and also according to the particular drug chosen as the "dope." The moderate and voluntary drinkers of alcoholic beverages who simply stop, will be no better and no worse in health, though better in pocket; if they substitute "near" drinks in moderation they will suffer no change in health, but if they increase their consumption of caffeine-containing beverages, they will be decidedly worse off. When prohibition becomes an established fact, the pretense that the consumption of light wines and beer in even the most moderate amounts is physically injurious will no doubt be dropped, and a new crusade will be started against some other social habit—probably smoking. And then there will not be wanting well-meaning but irrational medical men unable to see the difference between use and abuse and deducing from exceptions the rule, who will declaim against the evils of tobacco, and maybe at some future business meeting of our national medical society a resolution will be passed regarding the injuriousness of the cigarette, and this will be published as the deliberate scientific judgment of the greatest body of physicians in America. Then, after many days, the pendulum will swing back again.

THE UNIVERSITY OF LILLE DURING THE GERMAN OCCUPATION.

Professor Combemale in *La Presse Médicale* for January 9 gives an account of the four years' occupation of this institution by the Germans. The damage from bombardment was slight and quickly repaired. There was a tremendous explosion near the university buildings during January, 1916, the concussion of which was very destructive to apparatus and all other small perishable properties; but despite the havoc instruction went ahead as usual, although there was no way of replacing the damaged apparatus. Even the broken windows were not glazed for some days. The University Hospital —Saint-Sauveur—was requisitioned by the Germans for military purposes, and civilian patients were moved to private buildings in the neighborhood. In spite of all entreaties by the faculty, the entire equipment of the hospital became incorporated in full into the Germay army machine and could no longer be used for instruction or civilian care. The change, however, was gradual. Yet a great deal of the teaching and therapeutic installation, such as wax models and plates for teaching dermatology, was of no possible use to the invaders. Sometimes, after much red tape, a microscope or some other piece of apparatus was released, but this course was against the policy of the German heads of the hospital.

The military work done in the hospital varied with circumstances, and for several months at a time it was empty. The privileges of the university in the Charity Hospital were also encroached upon. Thus, while normally the university faculty had the use of 200 beds, one-half were appropriated by the Germans. Accommodations for civilians were cut in two at a time when there was much illness among the townsmen and refugees. The greatest interruption to the activities of the university came with the edicts of April, 1916, when a large part of the Lille population was virtually enslaved by the conquerors. The medical students, like other young men, were set at hard labor—not the entire body, but a certain number—and after a short period were promoted from rough manual to mental labors. The mode of selection of the victims is not stated. Another hardship was confiscation of metal apparatus for military needs. Even the platinum in use was seized. The general lack of fuel made it impossible to warm the rooms in cold weather. Professors who had coal then took the students to their houses. Finally, in May, 1918, the university buildings to the extent of three-fifths were suddenly ordered vacated without a word of explanation. The laboratory men were in fact formally dispossessed and their effects dumped bodily in the buildings which were to be spared. Apparently the object was wanton destruction, as there is no mention of removing the valuable installations to Germany. The buildings thus vacated were used for various purposes. Thus one became a telephone exchange, another a refectory, a third a dormitory

for employees, etc. The botanical garden was dug up to sink certain telephone cables. It was at this period that Germany realized her defeat, and these acts appeared motivated by malice alone, the establishment of the telephone plant being a mere pretext, since it could have been done elsewhere. Other university buildings were used for the railway bureaucracy.

About October it was evident that the Germans were slowly abandoning Lille. A general gutting of the place was begun, but apparently the university had nothing further to lose. During the more than four months after the dispossession of the professors these continued to lecture without much regard to time and place and held the annual examinations; and during the entire four years there was no break or defect in the teaching. The teaching body of the medical school and the students were submitted to less hardship than the university faculty and civilian population. The former could complain only of needless harshness, but the latter, as already abundantly shown, were treated with persecution and characteristic German brutality.

The Problem of Mental Deficiency.

Mental deficiency is one of the most serious problems that confronts civilization. The feeble minded constitute a direct and indirect racial menace. They are apt to breed their like and thus tend to deteriorate the standard of a population. If this goes on long the race and nation will suffer very greatly. The problem of the feeble minded is becoming more pressing, as the numbers of such are steadily increasing. How best to deal with the situation is exercising the minds of medical men and philanthropists and is even beginning to attract the attention of politicians. In Great Britain the matter is being considered in all parts of the country by committees appointed for the purpose. It appears to be the matured opinion of those who have made a close study of the subject that the only rational and effective way of dealing with mental defectives, in order that they may do as little direct or indirect harm to the race as possible, is to segregate them. Where the health, mental and physical, of the race is concerned, the happiness of the individual matters but little, and from this standpoint the safety of the country at large should be considered before the comfort of the defective, and therefore the feeble minded should be isolated. However, it is well known that defectives do not suffer from confinement in an institution, but are happier when thus cared for.

Influenza Pneumonia in 1837.

A writer in *El Siglo Médico* for December 7 has investigated in contemporaneous records an epidemic of influenza which in the above mentioned year visited France, Belgium, England, Holland, Prussia, Germany, and Spain. Whereas the coincidence of fulminant pneumonia and grippe has often been remarked, this author calls attention to the special prevalence of the former, which apparently rivaled that of the current pandemic. In London for a certain period the deaths averaged 1000 daily, the predominant cause being pulmonary complications. A contemporary French practitioner writes of the management of these malignant complications of the grippe, which gave to the epidemic a character *sui generis* necessitating a special plan of treatment. The complications were evidently largely bronchitis and bronchopneumonia. In the aged, in both the simple and pneumonic cases venesection was badly borne. Young and robust subjects were bled to tolerance and given Malaga wine. The application of a vesicatory "on the affected side" suggests that much of the pneumonia was lobar. Four ounces of Malaga wine were given daily until resolution of the lung was complete. Weak or elderly subjects were not bled, but treated with Malaga wine, pectoral remedies, and flying blisters. When the entire picture was that of frank pneumonia the habitual treatment of the latter with slight variations was used. This comprised a certain degree of bleeding, vesicatories, and tartar emetic in good dosage. Dr. Nonat, the contemporary in question, states that by means of these modes of treatment he obtained happy results.

Dr. Stephen Smith.

There is, ordinarily, no especial merit in the mere feat of having reached an advanced age, save as the length of years testifies to a clean youth and a sensible middle age, but when a man has not only far surpassed the Psalmist's time but has packed the long years full of good deeds and service to his kind, then indeed he is one whom all delight to honor. Dr. Stephen Smith, who rounded out ninety-six productive years on Wednesday of this week, is one who thus compels the affectionate homage of his colleagues and the admiration of the entire community which rejoices in his continued presence.

News of the Week.

The "American Journal of Care for Cripples," which is the only special periodical in English on provision for the disabled, becomes a monthly with its January issue, according to announcement by its editor, Douglas C. McMurtrie. Although dealing extensively with the rehabilitation of the invalided soldier, the Journal is in no sense a war product, as it is now entering upon its eighth volume. This periodical will contain in the future the studies, translations, and abstracts produced by the research department of the Red Cross Institute for Crippled and Disabled Men, which material has hitherto appeared in a special series of publications. The Journal also continues as the official organ of the Federation of Associations for Cripples.

Dr. Smith Ely Jelliffe, recently retired from the editorial management of the *New York Medical Journal.*

Influenza Fatalities in South Africa.—According to a statement made in the Assembly at Cape Town, the recent influenza epidemic in South Africa caused the death of nearly 129,000 persons.

Typhoid in Russia.—A despatch from Stockholm states that typhoid fever is prevalent in Petrograd, Moscow, and other places in Russia.

In one hospital in Petrograd twelve doctors and forty nurses have died from the disease.

Typhus Again Raging in Belgrade.—A despatch from Belgrade to the State Department at Washington, on February 11, states that typhus fever has broken out in the Serbian capital, especially among the Czech prisoners of war assembled there preparatory to repatriation, and among the Serbian soldiers arriving from the South. A United States sanitary corps, under Captain Stewart, is aiding the Serbian Government in fighting the epidemic.

French Death Rate far Exceeds Birth Rate.—Official statistics recently made public show that in 1913 the births in France outnumbered the deaths by 17,000. This slight excess disappeared in the following year, since which time the births have outnumbered the deaths. In 1914 there were 50,000 more deaths than births; in 1915, 1916 and 1917 there were each year nearly 300,000 more deaths than births, the total excess of deaths over births for these four years being 883,160. Births which numbered approximately 600,000 in 1913 dropped to 315,000 in 1916 and 343,000 in 1917, while the deaths increased, but not in comparable proportions, so that the total decrease in population was due to the great diminution in births and not to any great increase in deaths. These statistics do not include the 1,400,000 killed in war.

Bills in New York Legislature.—A bill has been introduced into the Legislature of New York State, known as the "calcimine and wall paper bill," which opposes the use of wall paper in sleeping rooms on the ground that many cases of blindness have been traced to the coloring matter in wall paper. At a recent hearing this bill was supported by representatives of the New York State Association for the Promotion of Public Health. Another bill before the Legislature provides for the transfer of the powers of the Department of Narcotic Drug Control to the State Department of Health. It is said that Governor Smith is in favor of the Health Department assuming the administration of the Narcotic Drug Law.

Annual Report of State Hospital Commission.—The annual report of the New York State Hospital Commission recently submitted carries a number of recommendations. Among these it urges the building of a psychopathic hospital for New York City, for preliminary treatment of patients and research work. It also recommends the enlargement of the Brooklyn and Creedmore branches of the Brooklyn State Hospital. The report shows that the State spent, during 1918, $10,494,000 for its insane, though the per capita cost per diem was only seventy-two cents. A total of 45,136 patients were treated in the thirteen civil hospitals, and 37,136 patients are now being cared for. Of those discharged 1,687 are said to have been cured. The report shows a marked decrease in the number of cases in which alcohol might be considered the cause of the insanity. At the close of the fiscal year fifty-two of the hospital physicians were on military duty. Dr. Charles W. Pilgrim is head of the State Hospital Commission.

Lenox Hill Hospital Rejects Merger Plan.—At a recent meeting of the members of the Lenox Hill Hospital the proposal to merge the institution with Columbia University was rejected and the trustees were instructed to break off all pending negotiations. One of the objections to the merger was that it gave to Columbia University eleven trustees and to the hospital only ten. The trustees of the hospital had recommended the merger believing that it would be an advantage to the hospital financially.

Children's Home Chartered.—The After Care Home for Crippled Children at 142 Bruce Avenue, Yonkers, has received a charter from the State of New York. Mrs. Matilda Danziger is the founder of the home.

Vanderbilt Clinic Expands Department of Oral Surgery.—Owing to the great need of a clinic in New York City for the care of injuries and diseases of the mouth, jaws, and face, the Department of Oral Surgery of Vanderbilt Clinic has been enlarged, reorganized, and supplied with the most modern surgical equipment. The latest type of *x*-ray and dark room apparatus have been installed, and men specially skilled in mouth and jaw radiography will have charge of this phase of the work. Patients referred to this clinic will receive prompt treatment and those needing hospital care will be admitted to one of the surgical services affiliated with the College of Physicians and Surgeons.

Free Clinic for Speech Defects.—The first free medical clinic devoted to the treatment of defective voice and speech conditions has been opened at 143 East 37th Street, New York. The clinic has as its objects to cure all forms of speech and voice disorders such as stuttering, stammering, lisping, nasality, cleft palate speech, etc. It will take care of defective teeth, mouth, or jaw conditions, when such conditions are the causative factors of defective speech. It will educate or re-educate patients who are deaf or hard of hearing. There will be evening classes three nights a week. The clinic will also maintain a Central Information Bureau and Clearing House for Speech and Voice Disorders.

Charities Aid Association Again Warns of Tuberculosis.—The danger of the development of tuberculosis following attacks of influenza from which recovery has not been complete has led the New York State Charities' Aid Association to issue a second warning, similar to that published several months ago, urging communities to call upon their physicians to hold tuberculosis clinics at frequent intervals. Persons who have had influenza are advised to submit every few weeks to medical examination, and those who are unable to pay a private physician for this service are advised to present themselves at a clinic.

Health Almanac.—The United States Public Health Service announces that its Health Almanac for 1919 is ready for distribution. In addition to the monthly calendar of health hints and notable events, it discusses the control and prevention of various infectious diseases, the disposal of human excreta, importance of clean drinking water, care of the teeth, care of milk in the home, etc. It also tells what the Public Health

Service is doing to protect the health of the people of the United States. Copies of the 1919 Almanac may be obtained upon application to the U. S. Public Health Bureau, No. 3 B Street, S. E., Washington, D. C.

The Medical Section of the American Life Convention will hold its ninth annual meeting at Signal Mountain Inn, Chattanooga, Tenn., March 26, 27 and 28, 1919.

Texas State Board of Medical Examiners.—Governor Hobby has appointed the following on the State Board of Medical Examiners: Dr. W. C. Swain, Dallas; Dr. C. O. Terrell, Eastland; Dr. S. L. Mayo, Bell; Dr. David Berry, Bexar; Dr. R. Y. Lacy, Camp; Dr. D. W. Davis, Jefferson; Dr. D. S. Harris, Dallas; Dr. E. Marvin Bailey, Harris; Dr. T. J. Crowe, Dallas; Dr. H. C. Morrow, Travis; Dr. M. E. Daniel, Fannin.

The Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases will meet at 41 East 123d Street on Tuesday, February 25, at 8.30 P. M. The paper of the evening will be read by Lieut. Commander William Seaman Bainbridge, M. C., U. S. N., on "Some of the Practical Surgical Lessons of the War."

The New York Physicians' Association will meet on Thursday evening, February 27, at the Chemists' Club, 52 E. 41st Street. The paper of the evening will be on "Internal Secretion," by Dr. Joseph Fraenkel.

Obituary Notes.—Dr. GEORGE W. SALTER, a graduate of the New York Eclectic Medical College, in 1889, died suddenly at his home in Brooklyn, on February 12, aged 68 years.

Dr. CHARLES ANDREW ROBERTSON, a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., in 1890, died at his home in Ridge Top, Tenn., on January 28, aged 50 years. Dr. Robertson was head of the Ridge Top Sanatorium for Tuberculosis at the time of his death and formerly a member of the faculty of the Sewanee Medical School.

Obituary.

WILLIAM F. MITTENDORF, M.D.,

NEW YORK.

DR. WILLIAM F. MITTENDORF of this city, who died at his country house in Crugers, Westchester County on February 14, was born in Germany in 1844, but came to this country as a young man. He was graduated from the College of Physicians and Surgeons of Columbia University in 1873, and, after study at the ophthalmological clinics of Holland and elsewhere in Europe, began practice in this city as a specialist in diseases of the eye. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, of the American Academy of Ophthalmology and Oto-Laryngology, the American Ophthalmological Society, the New York Ophthalmological Society, and of many social organizations. He is survived by his widow and three sons, two of whom are practising ophthalmologists in New York City. Dr. Mittendorf was a man of most engaging personality and enjoyed the friendship of a wide circle both within and without the medical profession.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 23, 1919.

The Interallied Fellowship of Medicine and the Harvard Medical Unit.—During last summer Sir Arbuthnot Lane, Sir James Mackenzie and Col. H. A. Bruce, the distinguished Toronto surgeon, who has occupied a high place in the Canadian Army Medical Corps throughout the war, made a tour of the United States with the mission to explain what was being done by the Medical Department of the British Expeditionary Forces, so as to indicate the directions in which close alliance could be established between that department and the medical service of the American Army in the last stage of the war, when the great Anglo-Saxon races would be fighting side by side. The British apostles received at the hands of the American medical public, both leaders and proletariat, a welcome of extraordinary cordiality, and on returning brought back to London the definite request from American medicine that London, for the future, should replace Berlin and Vienna as the Mecca for the English-speaking doctor; American science was open for the learning and instruction of Great Britain and her dominions, and similarly London should be open for the instruction and learning of America. The request was a reminder that the reproach should be removed that the American physician and surgeon, desiring to keep in touch with European movements and developments, had in the past sought the great clinics of Berlin and Vienna rather than the London medical schools, because the German races had brought order into post-graduate instruction, whereas in England no definite post-graduate instruction existed at all, and what there was was disorderly. That this is an accurate presentation of the position in London nobody can deny, but that the dawn of the fifth year of a great war was not a fitting time to start on the formation of a great post-graduate scheme was a fairly evident proposition. Then the shadow of a fifth year's fighting vanished, and some industrious and imaginative leaders of medicine in London determined that a start should be immediately made upon a real union of Anglo-Saxon medicine, with London as its European headquarters. In the new movement the Royal Society of Medicine, representing in its various sections all that is best in metropolitan and provincial science, became the center, and an Inter-Allied Fellowship of Medicine was founded, having for the time being its headquarters at the society. Sir William Osler, as a young man a successful Canadian professor, in early middle life a powerful force in scientific medicine and medical education at a great American medical school, and later Regius Professor of Physic in the University of Oxford, where medievalism and modernism run in double harness, was marked out as the chairman of the executive committtee formed to give effect to the scheme. Sir Arbuthnot Lane accepted the post of Hon. Treasurer, while the Hon. Secretaries chosen were Sir St. Clair Thomson, a famous laryngologist, equally as well known on the Continent as in England, Mr. W. Douglas Harmer, surgeon to St. Bartholomew's Hos-

pital, and Mr. J. Y. W. MacAlister, the secretary and librarian of the Royal Society of Medicine. Round these officers a powerful executive committee has been later collected, and the objects of the new alliance, as formulated by the executive committee, were stated this week in a speech by Sir St. Clair Thomson at a farewell dinner to the Harvard Medical Unit. The objects, as set out by Sir St. Clair Thomson, were grouped under four comprehensive headings: (1) The coordination of the resources of medical interest in England, so as to make them available for demonstration, (2) the initiation of schemes whereby facilities can be obtained for visits to, or courses of study in, the various British clinics, laboratories and museums, (3) the collection and distribution of information; and later the possible interchange of knowledge by temporary occupation of professorial chairs, and (4) the promotion of personal friendly intercourse. The primary object of the association is not, it will be seen, the formation of a great scheme for post-graduate study, but on the other hand each of the four objects demands such a scheme and forms a part of it.

The Dinner to the Harvard Medical Unit was the first public act of the new Inter-Allied Fellowship of Medicine, and proved a great success. The members of the Harvard Medical Unit have been during the week paying a short visit to London on their way home from France. The executive committee of the Inter-Allied Fellowship of Medicine invited them to an informal banquet at the Connaught Rooms, London, with a view to publicly thanking them for their enormous services to British arms, and at the same time of indicating that their action in fighting side by side with Great Britain was exactly typical of that racial union to promote which the Inter-Allied Fellowship of Medicine has been started. Lt.-Colonel Hugh Cabot, commanding the Harvard Unit, and in charge of No. 22 General Hospital, in an eloquent speech brushed aside the particular military performances of himself and his officers and insisted that the most important work which had been done by the unit was the bringing together of the medical profession on both sides of the Atlantic. He concluded his speech by saying: "It is to this bringing together of the British and Americans that we have most effectively addressed ourselves. We have been part and parcel of the British service and have given it the best that we had to give. At the same time, we have 'with a decent respect for the opinions of others,' maintained our own manners and customs, and have perhaps lived with a somewhat greater freedom and worked and played a little harder than sound British doctrine would sanction. We have been a gathering place for all sorts and conditions of men, and we desire to acknowledge the debt we owe to Sir William Osler and those associated with him in helping forward this mixing of professional men and women from both sides of the Atlantic." Other speakers at the dinner included Dr. Norman Moore, president of the Royal College of Physicians of London; Sir W. Watson Cheyne, M.D., member of Parliament for the University of Edinburgh, and lately president of the Royal College of Surgeons of England; and Sir John Goodwin, director general of the Army Medical Service, whose personality is familiar to many American medical men. Sir John Goodwin said that more than 150,000 British soldiers had been treated and cared for by the Harvard Unit during its stay in France and that the sentiment of brotherhood and affectionate feeling thus engendered must not be allowed to die down. The closing speech of Sir William Osler, who acted as chairman of the dinner, was an eloquent résumé of his personal knowledge of American medicine. He said that among the advantages of advancing years was the knowledge one might have of three generations, and this was his position with regard to the profession of Boston, which may be called the *cortex cerebri* of the United States. Oliver Wendell Holmes' Brahmin class existed in a larger proportion in the profession of New England than in any part of the English speaking world. It was a peculiar pleasure to him to welcome the Harvard Unit, which contained grandsons of men whom he had known well in the seventies. Opposite to him sat Major George Cheever Shattuck, whose father, Frederick Cheever (friend of student days in Germany and Professor of Medicine at Harvard) was the son of the distinguished George Cheyne, also a Professor of Medicine, the son of George Cheyne (*primus*), called after the famous English physician of that name, and son of Benjamin Shattuck—all of whom had practised medicine in Massachusetts—*caute, caste et probe*. Five generations of Warrens had served Harvard and the Massachusetts General Hospital—John, at present in the anatomical department, son of J. Collins, still alive and well and an honorary F.R.C.S., whose ancestors, Jonathan Mason, John Collins, and John Warren (the founder of the Harvard Medical School) were great figures in Boston. And there were many other medical families—as the Bowditches, Jacksons, Bigelows—which had given an hereditary distinction, as rare as it is valuable in the profession of any city.

The New England spirit—the keen sense of right and wrong, and the desire to help, inspired Harvard to send this Unit long before America could enter the war as a united nation. And with special reference to Lieut.-Col. Cabot he added: "The Unit was fortunate in the choice of the man who has had charge. Dr. J. William White, of Philadelphia, at the outbreak of war and until his untimely death, fought the battle for the Allies against Germany in a way I hope we shall here never forget. And our chief guest and his brother, Dr. Richard Cabot, early entered the propaganda, but they did not confine their work to the Eastern States where sympathy was largely with the Allies, but they went West to the strongholds of German influence and held public meetings, sometimes in the face of stormy and even disorderly opposition. A rude little rhyme about the Cabots indicates their position in popular opinion:

Here's to good old Boston,
The home of the bean and the cod,
Where the Cabots talk only with Lowells,
And the Lowells walk only with God."

The Interallied Fellowship of Medicine thus started should have a great future before it. Learning without priggishness, wisdom spiced with fun, and friendship ready to face criticism make up the spirit of the new society.

Conference of Tuberculosis Medical Officers.—

A conference of the tuberculosis medical officers of the United Kingdom is being held this week, and it is to be hoped that when the result of their deliberations is published it will be found to indicate the directions in which the prevention and control of tuberculosis can be much improved. Tuberculosis medical officers are, it must be understood, a definite part of the sanitary service of the country, and administered through the Local Government Board. The Medical Officer of Health, in localities where the populations warrant the establishment of such a staff, has working with, rather than beneath, him two assistant medical officers of health, one for education purposes and one for the public management of tuberculosis. The scope of the work of the assistant medical officer of health for tuberculosis purposes is indistinctly defined, for his duties must frequently impinge upon the general duties of the medical officer of health for sanitary or epidemic purposes, and on those of the assistant medical officer of health for educational purposes, whose particular clientèle will continually include many tuberculous children. And not only do the relations of the tuberculosis medical officers to the public health service of the country, as a whole, require adjusting from the point of view of function, but the conditions of their service, the uncertainty of tenure, the scale of pay, the opportunities for advancement, the provisions for pension, all require more fair and thorough investigation than they have yet received if a comprehensive and united policy for the control and eradication of tuberculosis is to be pursued by the country, either under the existing dispensation, or under the reign of a new Ministry of Health. The medical officers of sanatariums for the tuberculous, the directors of open air schools, the superintendents of chest hospitals and farm colonies—all these valuable officials are concerned in making the position of the tuberculosis medical officer one that will be desired by good men, and will be provided with facilities and inducement for good work. The conference is being held at the instance of the Tuberculosis Society at the Royal Society of Medicine.

The Reward of Patriotism.—The temporary medical officers with the army are feeling intensely aggrieved at the proportion of honors and decorations which have accrued to them in comparison with the regular officers of the Royal Army Medical Corps. As the latter were only discharging their official duties, while the temporary men, mainly as volunteers, were replying to the call of duty by wholesale sacrifice, in many cases, of their material interests, it would not have been surprising if the decorations and honors had been mostly bestowed upon the latter—for no one suggests that they did not take equal share in all risks and earn equal scientific credit. During 1917, however, and for example, the proportion to deaths of grants of the D. S. O. (Distinguished Service Order) among the regular officers was 25 times higher than it was among the temporary officers.

New Views in Criminology.—Dr. Charles A. Mercier has just been made the recipient for the second time of the Swiney Prize of the Royal Society of Arts, which is awarded for the best essay published during the year on a medico-legal subject. Fourteen years ago Dr. Mercier published a work entitled "Criminal Responsibility," in which he maintained the thesis that in criminal charges justice should take into consideration the grades of responsibility as a guide to liability for punishment. That was not so much a new doctrine as an exposition and extension of certain conclusions of the eminent judge, Sir Fitzjames Stephen, in his "History of the Criminal Law of England," and the book established Dr. Mercier's position as a lawyer as well as a psychologist, though some of the points made in a very controversial performance were of a hair-splitting nature, and though some of the views advanced did not receive general acceptance. The Swiney Prize essay, entitled "Crime and Criminals," is a complement to the earlier work, and for the complete following of its arguments the reader might be expected to have before him not only "Criminal Responsibility" but also two pamphlets entitled "Primary Insanity" and "Human Temperaments" as well as the author's "Textbook on Insanity and Other Mental Disorders." All these books show Dr. Mercier to have an extraordinarily clear-cut conception of the nature of crime and of the proper definition of insanity. His summaries of the normal human temperament and of the influence upon that temperament of individuality and environment are convincing, and the various interrelations of these conditions and factors as they manifest themselves in reality afford him endless opportunities for wit and wisdom, of which he makes good use. Sir Bryan Donkin, a member of the board of directors of convict prisons, points out in a brief introductory note to "Crime and Criminals" that throughout his latest work Dr. Mercier takes the view that the study of crime and its causes is properly the study of all antisocial actions of individual offenders. Dr. Mercier, in effect, states that any science of criminology can be founded on generalizations drawn from observations upon convicted criminals *en masse*. It hardly seems to require Sir Bryan Donkin's great experience to support such a view; everyone knows that knowledge of physiology must precede that of pathology. But Dr. Mercier's attitude throughout the book suggests that he feels himself to be at variance with other psychologists on this and many other points in the natural history of crime and its perpetrators. The attitude of perpetual opposition to his professional brethren, whether justifiable or not, becomes irritating to the medical reader, while the lay reader will derive the idea that save Dr. Mercier all psychologists are fools. But I strongly advise all you readers to get this book because it is a remarkably able presentment of the difficulties arising in the legal treatment of crime, and of the arguments which should sway the medical mind in regard to all such questions.

Period of Incubation of Grippe.—A soldier was interned for grippe, but observation showed that he had simple bronchitis. Having been placed in the grippe ward he developed that affection, the chill appearing just 47 hours after his reception into the latter. English observers have timed the incubation as 41 to 45 hours in one case, 47½ hours in another, etc., and there is sufficient evidence accumulated to fix the incubation period conventionally at about 48 hours.—*Le Progrès Médical.*

6. Pathogenicity, Cultivation, and Reproduction of Protozoon Parasites.—A. J. Hinkelmann has come to the following conclusions: (1) The ameba, the *Balantidium coli*, the *Cercomonas hominis*, and the organisms of the trichomonas group constitute a group of organisms that are parasitic to man, and, in common, induce the same pathological conditions with different degrees of severity. (2) The infection by any of these parasites may become generalized through the entrance of the organism into the circulation, after which metastatic lesions in various parts of the body may result. (2) The kidneys are especially prone to the infection, on account of their function in the process of elimination. Remnants, or whole and living organisms, may appear in the urine; and in the case of amebiasis is a valuable diagnostic point. (4) Diarrhea and gastrointestinal disturbances are common clinical manifestations of infection caused by these organisms; but have many degrees of severity, or may be altogether absent. (5) The metastatic lesions, especially in amebiasis, may be manifested directly and apparently as the primary condition. (6) Protozoon parasites may be recovered alive and active from the blood through the method of hemolyzing freshly drawn blood with distilled water and centrifuging. (7) the *Balantidium coli* may be recovered from the blood in culture by placing the blood into sterile distilled water in the proportion of 1 c.c. of blood to 200 c. c. of water. (8) Amebiasis may be suspected in all cases of obscure fever showing a striking difference between morning and the evening temperatures with the leucocyte count remaining steadily about 12,000, regardless of the presence or absence of diarrhea or any suggestive intestinal symptoms. (9) In semi-tropical countries sudden pain in the abdomen with rigidity and fever is not always indicative of appendicitis, but may be caused by an abscess formation due to protozoon metastasis; especially if the leucocyte count rises above 12,000 and does not agree at all with the acuteness of the case. (10) Chronic languor, pallor, emaciation with an eosinophilia and a stubborn constipation, may mean a swarming infection of the *Trichomonas intestinalis* high up in the intestinal tract. (11) Skin eruptions may be caused by protozoon invasion of the blood. (12) These protozoon parasites appear, in varying degrees, to have everything in common. They act alone, or in conjunction with one another; and conditions which predispose an infection by one do so for the others as well. Immunity can not be established, but a valuable amount of resistance appears in all individuals, which combats the invasion in the beginning. When this resistance becomes broken down, the case becomes chronic in some form or other; or the patient succumbs to an overwhelming proliferation of the invading organism, in an acute attack, depending upon which one of the group he has to contend with.

5. Trench Fever: A Critical Review.—Wilder Tileston points out that though trench fever was very prevalent in the British army in France, it was much less common in the French, Italian and German armies, and has occurred only in isolated instances in the British armies elsewhere. The onset is sudden, the first symptoms being dizziness, headache, and pains in the lumbar region and legs, associated with fever. Chilliness is common, but true chills are unusual. There may be vomiting. Headache is not very severe and is more often frontal; in some cases it may be occipital and associated with neck stiffness. Lumbar pain is so severe that smallpox is suggested. In the legs it is first muscular and later becomes localized to the tibiæ; it is rarely in the joints. There is pain in the splenic region; abdominal pain is common and appendicitis may be simulated. An accompanying symptom is a well marked hyperesthesia of the skin on the outer aspects of the legs, on the thighs and in the precordial and left axillary regions. This hyperesthesia is a sign of considerable diagnostic importance, as it is rarely seen in diseases likely to be mistaken for trench fever. Prostration is frequently marked, but may be absent. Constipation may be present, but is not the rule; diarrhea is absent. Eyes are bright and conjunctivæ are injected. though there is no exudate. Nystagmus on lateral motion of eyes occurs in about 85 per cent. of cases as an early and persistent sign. Herpes is rare; tongue is clean or slightly coated. The respiratory tract shows no sign of inflammation and the pulse rate is usually low, but with relapses there is a tendency to tachycardia. Though many writers have stated that the spleen is not enlarged, the American Red Cross Commission found palpable enlargement over some period of the disease in 85 per cent. of cases, and within a few hours of onset in 25 per cent. This enlargement may be encountered at any stage of the disease and sometimes persists only for a day or two, which may explain the fact of its being overlooked. In about 50 per cent. of cases a characteristic but evanescent rash appears, consisting of scattered red macules about the size of rose spots which disappear with pressure and are rarely elevated; this occurs generally on the trunk in successive crops during the original attack and in relapses. Blood examination may reveal a leucocytosis, or in some cases a leocopenia. At the time of a relapse, the picture is more or less characteristic in that neutrophils, lymphocytes, and large mononuclears are all simultaneously increased. Urine rarely shows albumin or casts. McNee, Renshaw and Brunt have distinguished two types of trench fever according to the temperature curve; the short and the long. In the former there is usually an intermission of fever about the third day, followed by a rise after a day or two of normal temperature. The patient becomes afebrile at the end of 7 or 8 days and recovers promptly or suffers a single relapse. In the long type there are usually three or four relapses, occurring at regular intervals and resembling the attacks in ratbite fever. The interval between relapses ranging from four to thirteen days and is usually fairly constant for the individual case. During relapse the temperature is often as high as in the original attack, but rarely remains up for more than 36 hours. The tendency is for the fever to be lower at each relapse and between attacks the patient feels fairly well except for slight pains in the shins. There is also a chronic type of this disease which lasts for many months, following an acute attack. The patient suffers from pains in the shins, aggravated at night and upon exertion. The temperature shows a slight rise in the evening to 99.5 degrees or 100 degrees, and from time to time there may be a slight further rise with increased pain in the shins. Complications are absent, hut soldier's heart is a fairly common sequel. McNee, Renshaw and Brunt have shown the causative agent of trench fever to be an infectious organism. They were able to transmit the disease to healthy

soldiers by intravenous or intramuscular injection of whole blood, and also by the blood of such experimental cases. Experiments with washed red corpuscles were successful, while those with plasma and serum were inconclusive. Filterable plasma and serum and filtered extracts of red corpuscles did not produce disease. The organism is probably contained in the leucocytes and is non-filterable. These experiments have been confirmed by the Trench Fever Commission of the Medical Research Committee of the American Red Cross. Plasma, serum, and extracts of red corpuscles after being passed through a Berkefeld filter did not reproduce disease, and the blood was shown to be most infectious during the first two days of fever and more so in the original attack than during relapses. It was concluded, therefore, that the organisms were contained in the blood and probably in the plasma and that some were thrown down with the red cells during centrifugation. Search for the organism has led to conflicting results. The relapses at regular intervals and the temperature charts suggest a spirochetal infection and these organisms have been found in the urine. Stoddard, however, has shown that this may occur in healthy men. Dimond has isolated hemogregarines in the peripheral, splenic, and hepatic blood in twelve cases of trench fever, but his findings have not been confirmed. Blood cultures have yielded negative results, save that Houston and McCloy have reported the presence of an enterococcus. Animal inoculation has been negative. From the experimental work of Davies and Weldon, it appears certain that transmission is usually effected through the body louse and it is probable that the organism is harbored by the lice and that infection is not purely mechanical. Byam and his associates have shown that infection is transmitted also by the excreta of lice rubbed into the scarified skin, after an interval of seven days or more from the time of feeding on a trench fever patient; this suggests the possibility of a developmental cycle within the body of the louse. Lice were found to remain infective for at least 23 days. Infection has also been transmitted by the Red Cross Commission with filtered urinary sediment and with filtered louse excrement, so that the organism may be regarded as filterable. The virus resists drying and moist heat at 60° C. for thirty minutes, a temperature which kills lice and their ova, but is killed by 70° C. for the same length of time. In regard to immunity, Byam succeeded in reinfecting a patient who had completely recovered from the disease. The incubation period under natural conditions appears to be from 14 to 24 days; when the disease is produced by blood inoculation it is from 5 to 24 days, and in experiments with lice from 16 to 35 days. In the absence of fatal cases the pathology is unknown. Trench fever may be distinguished from influenza by the facts that prostration is usually less and there are no signs of inflammation of the respiratory tract in trench fever, whereas in influenza the shin pains and relapsing type of fever are absent. From dengue it may be distinguished by the character of the eruption, the presence of leucocytosis and the fact that dengue has never been reported north of 41 degrees latitude. Examination of the blood excludes relapsing fever and ratbite fever may be excluded by the history, absence of enlargement of the regional lymph nodes, and the type of eruption. From typhoid and malta fever, trench fever may be excluded by the clinical course and by cultural and serological methods. Prophylaxis depends upon destruction of lice. No effective method of treatment has as yet been devised. Rest in bed probably shortens the course of the illness. Salicylates and coal tar products are indicated for the pain, and morphine may be necessary in severe cases. Dimond reports relief of pain from lumbar puncture. Serum injection has been ineffective, as is arsphenamine. Thyroid extract is recommended by Byam for irritable heart in chronic cases. Detailed reports of experimental work on this disease are included in the report of the American Red Cross Trench Fever Commission, published by the Oxford University Press.

4. The Prevention and Treatment of Diabetic Coma. P. J. Cammidge.

4. The Prevention and Treatment of Diabetic Coma.—P. J. Cammidge points out that coma may occur early or late in the course of diabetes mellitus, but is particularly prone to develop during the first year of treatment and is more common under than over forty years of age. Exaggerated respiration without cyanosis or evidence of physical cause often appears with dramatic suddenness, inspiration becomes prolonged like the breath preceding a yawn, while expiration becomes forced and more complete than normal—the socalled air-hunger of Kussmaul. A characteristic sweet, fruity odor of the breath is noticed occasionally and may suggest the cause of the air-hunger. The face has an anxious expression, is sometimes flushed, often pale and drawn and of a yellowish tint; the eyes are generally half-closed, the pupils react to light until deep coma occurs and are usually dilated, less often contracted. Softening of the eyeball, due to a fall in the intraocular pressure, is an early and important sign of diabetic coma. The pulse is soft and accelerated, but rarely exceeds 120 a minute. Blood pressure is low. The usually subnormal temperature rises with onset of coma to about 100°, but may fall as low as 90° as death approaches. The extremities are cold and there may be slight edema of the feet. Although coma may develop suddenly, as a rule it is preceded by suggestive symptoms; these, however, may be so slight that they may be overlooked. Regular examinations of the urine, blood, and alveolar air furnish indications of the probable onset of the complication. Ever since Stadelmann in 1883 discovered oxybutyric acid in the urine in cases of severe diabetes, it has been recognized that diabetic coma is usually associated with a high degree of acidosis, accompanied by the presence of acetone bodies in the urine. The appearance of these bodies is usually the first sign of commencing acidosis. The ammonia output of the urine is increased from 0.5 to 1 gram per day to 10 or even 12 grams, and as a rule an excretion of 4 grams a day rarely exists for more than a few days without coma developing. Whereas normally the ammonia nitrogen constitutes 4 to 5 per cent. of the total nitrogen of the urine, as coma becomes imminent this percentage may rise to 40 or 50. A useful indication of serious acidosis is a diminution in the available carbonates circulating in the blood; this may be determined indirectly from a lowering of the carbon dioxide of the alveolar air, which can easily be estimated by Mariott's device, or directly from the blood itself. The results of alkaline therapy, on the whole, have been disappointing and it can hardly be claimed that the death rate has been improved by it; it is a symptomatic treatment which does not touch the source of the trouble, the excessive formation of organic acids. Moreover, large doses of alkali often cause irritation of the gastrointestinal tract, or if given in very dilute solution overburden the stomach by the large amount of fluid and throw excessive work on the kidneys. When taken over long periods, alkalis interfere with digestion, deplete the body of necessary salts, and have a depressing effect on the heart; finally, as Joslin has pointed out, it is possible that their administration may set free acid bodies existing combined, quiescent, and harmless in the tissues and so do harm. Furthermore, Allen's experiments have shown that in diabetic dogs no apparent prolongation of life results from keeping the alkaline reserve of the body normal with alkalis given intravenously or by mouth. Rosenfeld, Hirschfeld, Levy, and others have shown that fat is the chief source of the acetone bodies and that they are derived mainly from the fat of food. The careful control of the fat intake in the diet is one of the most certain practical methods at present at our disposal for preventing acid intoxication and subsequent coma. By this means Joslin reduced his death rate through coma from 64 to 44 per cent. Systematic control of the fat intake in diabetes has hitherto been neglected for the following reasons: (1) The prevalent idea that diabetes is merely a defect of carbohydrate metabolism; and (2) the doctrine that loss of weight by diabetics must be prevented at all costs. Both ideas are erroneous. Diabetes is not a mere inability to assimilate glucose; it

is a defect in the metabolism of carbohydrate, protein, fat, and probably mineral substances as well. Treatment from the first must be based on the hypothesis that a general failure of metabolism is involved. The weakened metabolic functions of the diabetic are capable of dealing with only a definitely limited load or failure of the metabolic processes occurs. If the amount of carbohydrate in the diet is reduced but the total intake of food maintained by adding fat or protein, the metabolic functions will still be overtaxed and the downward progress of the disease will continue. The case will have the characters of a progressive diabetes with steady fall in carbohydrate tolerance, a type frequently met with. If, however, such patients are allowed to lose weight until the body mass is reduced to a level that can be maintained by a total load of food below that which can be efficiently dealt with by their defective metabolic powers, the progress of the disease is checked. Muscular efficiency and weight are not synonymous, and a thin patient feeding within his metabolic limits can do more and is less easily tired than one who is attempting to maintain a hypothetical weight for an individual of his size. It is probable that the death rate from coma may be materially reduced if regulation of the fat intake is exercised from the earlier stages of the disease. Coma is the consequence of autointoxication, but the evidence available suggests that it is a toxemia resulting from a general failure of metabolism rather than a specific toxin; it may be produced by several toxins of different origin acting together. In some cases the metabolic defect may be more complete or rapid in one direction and there may be associated defects in excretion, as in interstitial nephritis. Some of the symptoms met with during the onset of diabetic coma may be the result of the dehydration of the tissues produced by a high concentration of sugar in the blood; and this may also explain the frequency with which coma is precipitated by gastrointestinal disturbances, particularly when there is vomiting or diarrhea, and by conditions where large inflammatory exudates take place. Cases of fatal coma have occurred in which there was no evidence of acidosis and in which air-hunger was absent. These facts favor the argument that toxins other than the products of defective fat metabolism—for instance, those due to imperfect metabolism of protein—may be responsible for the condition. Experiments commenced by the author, but abandoned temporarily, seemed to show that protein metabolism tends to become less and less complete as the disease progresses; this with the presence of amino acids in the urine points to the onset of coma being associated with the failure in the functional activity of the liver, and it seems likely that the resulting imperfections in protein metabolism may be a contributory factor at least in bringing about the condition. A striking increase in the calcium and magnesium loss in the urine is a constant feature in diabetes, and it is possible that this renders the nervous system more susceptible to the action of toxins. It would appear, therefore, that the only "cure" is to prevent all possible causes that may give rise to the condition by so arranging the diet that (1) the patient's tolerance for carbohydrate, protein, and fat is not exceeded; (2) the total load of food is within his metabolic capacity; (3) the diet is correctly balanced; and (4) a sufficient allowance of inorganic salts is provided. If this is done a surprising improvement may be manifest even in advanced cases. The diet must be arranged to fit the patient's metabolic capacity, not his appetite. The treatment of cases with coma should be as follows: Rest in bed and avoidance of disturbing influences; the bowels should be cleared, but excessive purgation avoided; 2 ounces of lemon juice and small amounts of potato and gruel may be given at three or four hourly intervals for twenty-four hours, and the patient should be encouraged to drink as much liquid as possible. If there is vomiting, intravenous injections of saline should be given. After the twenty-four or forty-eight hours the carbohydrates may be omitted for a day or two. Joslin has claimed that better results can be obtained if alkalis are avoided and injections of normal salt solution or even tap water are given. If speedy improvement, however, does not follow the latter, alkaline injections should be given, particularly if there is uremic element. Cardiac stimulants should be administered—digitalis subcutaneously or by mouth, or strychnine, caffeine, alcohol, ether, camphor, ammonia, or pituitary extract may be useful. The administration of oxygen is useless, since the difficulty of respiration is not due to lack of oxygen.

3. Pelvic Measurement in Ante-Natal Clinics. A. W. Bourne.
4. Primary Sarcoma of the Prostate: Rapid Growth Following Injury. David Newman.

1. The Climacteric of Life.—Guthrie Rankin submits a clinical survey which shows the importance of the climacteric period of life, not only in women but in both sexes. The history of every life is a gradual ascent from the time of birth till its fastigium is reached, and from that point one of decline until it finds its termination in death. The climacteric period, which coincides with life's full maturity, is the time of special liability to the development of disease, hereditary or otherwise. It is well recognized in women, but it is not so generally appreciated that men go through a similar readjustment of tissues, though probably at a later age. Since at this time the protective powers of the body are less active, acute illness is attended with more than average risk. The immediate counterpart in man of the ovarian changes which take place at this time in women is probably to be found in the structural alterations which become established in the prostate gland. It is not surprising that growths of malignant type so often date their inception from this period of unstable tissue life. Most interest, however, attaches to the chronic ailments met with at this period of life, and the author selects three that are commonly met with in men and three more usually encountered in women. Although each ailment may be considered as an entity, they are each related to the other and none is really self-contained. Arteriosclerosis, interstitial nephritis, and diabetes form a group frequently seen in men between fifty-five and sixty-three. Each may be regarded as evidence of a breach of tissue integrity, and in all three cases the common causative antecedent is continued strain—domestic trials, financial worries, emotional storms, and mental anxieties. The stress of carrying on falls primarily upon the nervous centers, the result being neurasthenia. More often than not these ailments overlap one another, and all three are frequently seen together, and their close association makes the onset of one almost certainly the prelude of the others. The indications as to preventive treatment are simple: the strain of life must be ruthlessly curtailed; work must be lessened and leisure cultivated; the diet must be adjusted to the necessities of the condition and the capacity of the damaged organs. A weekly grain of calomel will provide for free action of the liver, and periodical small doses of iodide and nitrate of sodium with arsenic will help to keep the blood tension low, and possibly aid in delaying the thickening of the arterial walls. In cases of interstitial nephritis, the amount of urea in the urine is of more importance than the quantity of albumin. Marked diminution of urea is an evil omen and should be followed by complete rest in bed, a milk dietary, mild alkalis, and free hepatic stimulation. The occurrence of albuminic retinitis is of grave prognostic importance. In diabetes the treatment resolves itself into a suitable restriction of diet and the exhibition of opium. Starvation is not to be recommended in patients of this age; it imposes too great a tax upon the nervous control and imperils serenity of temper and happiness, and in any case the sugar ultimately returns. In younger patients this procedure has much to recommend it. Upon the first appearance of diacetic acid the patient should be put to bed, treated with a more rigid dietary as regards carbohydrates and with a temporary withdrawal of fats, purged moderately, and given bicarbonate of soda with taraxacum in full doses every three or four hours. A reasonable amount of alcohol should be allowed. In women, colitis, rheumatoid arthritis, and hyperthyroidism are the ghosts most to be dreaded at the "change

of life." Women as a class are more careless than men in the proper regulation of their bowels and, suffering from constipation, soon fall into the "aperient habit." In time the tone of the colon suffers, with colonic irritation as the result. The mucous membrane of the large intestine becomes impaired with displacement of abdominal contents. An ulcerative process may supervene which it is difficult to repair; there are niggling pains, troublesome irregularity of bowels, flatulence, and unpleasant borborygmi. Toxemic consequences cause the patient to look ill, impair the general nutrition, and may end in a marasmus almost as pronounced as that produced by malignant disease. Rheumatoid arthritis is almost always rebellious and leads to permanent and characteristic deformity. When the disease invades the vertebral column the miseries and helplessness of the patient may compel for a time complete rest in bed. Until the pathological process has been arrested there is constant risk of intercurrent acute exacerbations, when the joints become red, swollen, and painful, to the accompaniment of disturbed digestion, pyrexia, and a condition of neurasthenia. Fibrositis, sciatica, and lumbago are to be feared as hindrances to the progress of recovery. Graves' disease, though generally met with in an incipient form, may pass from that stage to fuller development, and end in exophthalmic goiter. Even in its minor degree it is accompanied by disturbance of the nervous system, and sometimes leads to a mild degree of mental aberration. The thyroid gland may become enlarged apart from any change in the eyes. Every case is associated with a risk of glycosuria, which from small beginnings may end in a permanent diabetes. Intestinal difficulties are common and the colon may prove troublesome. Pigmentary changes in the skin may declare themselves in the form of leucoderma, and patches of alopecia sometimes becomes established on the scalp. The causative influence in all three conditions is probably a toxemia, by which metabolism is more or less seriously interfered with. Treatment, therefore, should be directed toward combating toxemic intoxication. In colitis douches are sometimes useful, but they may create an undesirable reflex action upon a nervous system already touchy. Beta-naphthol, bromide of ammonium, and bismuth is a useful combination, to which may be added an occasional dose of calomel or podophyllin. A tablespoonful of liquid paraffin should be taken before breakfast every morning. The abdominal wall may be supported by wearing a suitable belt. In rheumatoid arthritis guaiacum is an efficient remedy and should be used in combination with sulphur. The usual treatment by bromides, strophanthus, thyroidin, and arsenic is indicated in cases of hyperthyroidism. In both sexes, however, the success of treatment lies in convincing the patient that the years are beginning to tell their tale and that a new and more subdued plan of life must be adopted.

The Epidemiology of Cholera at Berlin in 1918; The Epidemic of Cholera in the Autumn of 1918 at Berlin.—The first of these two papers, by E. Seligmann, and the second, by Magnus-Levy, are devoted to the epidemiology and symptomatology of this affection. It will be remembered that the Wolff Agency denied in the lay press that Berlin had been the victim of cholera in the fall of 1918. Of unknown origin, the epidemic began with an employee of the slaughter houses. The inquest held upon several other cases of cholera revealed that they all came from the same meat storage plant in which this employee had worked. The measures put in action following this inquest soon put a stop to the spread of the epidemic. The mortality was 14, or 77 per cent. This extremely high percentage of deaths is explained differently by the two contributors. Magnus-Levy still insists upon the diagnostic value of the "deep expansive respiration," similar to that met with in diabetic coma or in certain instances of uremia. The impression one gets from reading the two papers is that Berlin was hard hit, although the number of cases is eighteen. Perchance were this multiplied by several zeros the correct number of cases might be surmised.

The Treatment of Radiologists' Hands.—G. Holzknecht states that the lesions developing in professional radiologists, among whom are to be found many physicians well used to radiography, are to be considered as precancerous lesions. Instead of surgical removal, which gives rise to cicatricial retraction, the writer is of the opinion that radiotherapeutic treatment is indicated, either with the *x*-ray or radium. The fear of treating these lesions with radiations is disproved by daily practice, but the writer insists upon the use of filtered rays. Of fifty cases treated only three had to have excision of the lesion performed; the others, among whom there were several cases of rapidly progressing ulcerating epitheliomata, rapidly recovered. The dosage was: *x*-ray: 10 to 12 H filtered through 4 millimeters of aluminum at once, or two to three seances of 6 H filtered through 4 millimeters of aluminium at intervals of a fortnight. With radium, 4 milligrams of metallic radium per cubic centimeter of surface were employed filtered through 2 millimeters of silver. Seances lasted from one to eight hours with interposition of a thin layer of cotton padding.

December 3, 1918.

The Serology of Typhus Fever, Especially from the Viewpoint of Immunization with the Proteus X 19.—H. Werner and E. Leocreami have attempted the immunization of subjects chosen among a population greatly exposed to typhus fever, by means of an injection of dead proteus X 19. After a certain dose has been obtained the reaction of precipitation, which was at first negative, becomes positive, the volume of the precipitation thus obtained reaching 1/800 or even 1/3,200. Local and general reaction was insignificant. Of the twelve subjects treated none contracted the disease, although in their families 20 per cent. developed typhus. However, on account of the small number of experiments, the writers do not draw any decided conclusions from the results obtained. Examined from the viewpoint of their resistance to heat, the agglutinins thus produced in human blood serum resist up to the temperature of 65° C. Experiments with the sera of convalescents had already shown that these so-called "immune sera" (acquired immunity after infection) did not resist a temperature above 60° C. When in presence of bacterial emulsions the sera studied by the writers offered a marked absorption of the agglutinins by the proteus X 19. The writers refer to a peculiar property of these sera, namely, that they coagulate the bacilli of typhoid, while the bacillus paratyphoid A and B escape this coagglutination. However, this property is not constant. As to Wassermann, artificial immunization against proteus X 19 is without influence on it. From an entirely different viewpoint the writers have noted that the agglutination acts quite as much on dead as on living proteus X 19.

Abdominal Phenomena in Gunshot Injuries of the Spine.—S. Weil recalls, with case reports, that wounds involving the spine may give rise to a peritoneal syndrome simulating a wound of some of the abdominal viscera. The article contains nothing new, the subject having been as fully covered during the past three years in several excellent papers by the French surgeons.

The Treatment of Peritonitis with Ether.—G. Wolfsohn has obtained good results by introducing ether into the peritoneal cavity at the dose of 50 to 100 c.c. during laparotomies for generalized peritonitis. It is to be pointed out, nevertheless, that from what he would lead us to infer his cases were operated on very soon after perforation of the appendix, intestine or stomach had occurred, a fact which tends to remove from this treatment the writer's mortality, which is rather high (18 per cent.), given the circumstances in which he operated.

Deutsche medizinische Wochenschrift.

December 5, 1918.

The Pathology and Clinical Indications of Blood Platelets.—V. Schilling refers to our present insufficient knowledge as to the origin of blood platelets. In place of the various theories which have been proposed for their autogenesis the writer defends the idea that their origin is to be found in the nuclei of the erythrocytes,

and to back up this explanation he describes the formation of the platelets, which can be followed under the microscope in a perfect way. They are completely absent in fresh blood, while very slight disturbances of the circulation free them from the younger forms of erythrocytes, either because they are included within the red blood corpuscle or are adherent to it. Other arguments are in favor of this manner of viewing the subject, namely, absence of the platelets in organisms having nucleated red blood corpuscles; their appearance during autogenesis at the time when the nucleated cells take the place of non-nucleated cells and at a time when the leucocytes have not as yet appeared; the chemical make-up of the platelets (nuclein) is still another proof of their nuclear origin. The writer studies the relationship of the platelets to coagulation, as well as the clinical meaning of their variations. Their increase implies an exaggerated formation of erythrocytes (chlorosis, mild secondary anemia, polyglobulia, scurvy, etc.), their decrease signifies an insufficiency of hematopoiesis (infections, intestinal intoxication, essential anemia, leucemia, etc.).

A New Procedure for Detecting Gastric and Duodenal Ulcer.—L. Freund describes a method which permits one to make an estimate of the sensibility of the mucosa to electric currents and thus detect possible erosions. The stomach is in the first place filled with a barium mush, a gastric catheter furnished with a metal wire fulfills the office of an internal electrode, while a roller placed on the body surface represents the second electrode, which is passed over the gastric area over the front and back. The current is furnished by an ordinary faradic machine with a medium separation of the coils. The patient either complains or not of pain, which is more marked at certain points and can thus serve to localize an ulcer. The writer thinks that this procedure may render considerable service, although he has employed it in a very limited number of cases where a control autopsy could be made.

La Presse Médicale.

December 19, 1918.

Symbiosis of Chancre and Vincent's Ulcer.—Payenneville states that this association has been seen in this fashion, that the ulceromembranous buccopharyngeal affection known as Vincent's angina or stomatitis has coexisted with primary syphilis. It is known that the exciting causes of Vincent's disease can cause lesions anywhere in the body, even on the genitals; and the author has seen the coexistence of the spirochete of syphilis with that of Vincent's disease along with the fusiform bacilli which are also present in that affection. The technique in examining for the treponema ought therefore to be carried out in such a manner as to include a research for the organisms of Vincent's disease. The importance lies in the fact that Vincent's disease when associated with a chancre would be mistaken for secondary syphilis. The author imagines a case of typical Vincent's disease in its usual locality in which examination of tonsillar smears showed also the presence of the treponema. In the clinic he saw a woman who presented an ulcer of the labium majus which had a diphtheroid coat. It bore every likeness to a chancre and there was inguinal adenopathy. The duration was about a month. Smears showed the ulcer to be due to the organisms which cause Vincent's disease. The treponema was absent. On the other hand, the Wassermann was positive. By technical refinements it became possible to discover the treponema. After discussing the more recent methods for staining the latter, he decides on the superiority of Harrison's, who substitutes for the India ink of the Burri method collargol in aqueous solution. The latter is first dropped on a slide and the serosity to be examined is added, one or two drops, and the two fluids mixed and dried. The treponemata show the stain, but if Vincent's spirillum and fusiform bacillus are present they remain unstained. The ultramicroscope is used in Harrison's test. The treponemata are not actually stained, but the staining of the background makes them visible. The other organisms are recognized as fine white threads on the mahogany background.

La Presse Médicale.

January 2, 1919.

Phlebitis and Septicemia.—Dehelly, who has been associated with the Rockefeller Institute Hospital and who has done much in collaboration with Carrel, relates a case which occurred in the War Service of that institution. Septicemia can mean only a condition in which living pathogenic bacteria circulate in the blood. In March, 1918, a Hoboken fireman was interned ten days after sustaining a fracture of the lower third of the leg. This was associated with fracture into the ankle joint and, on admission, the joint was exposed and suppurating. Gangrene had also set in and crepitus could be obtained. An amputation was performed at the middle third of the leg. Clinically the condition was very threatening for the first days, but thereafter the patient did well and made a good recovery. The untoward symptoms were chills and high temperatures and blood cultures then showed living streptococci of the hemolytic type. The apparent improvement was therefore regarded as a mere remission. Nothing was indicated locally and some electrargol was thrown into a vein, but had evidently no bearing on the favorable outcome. While there were no further general symptoms the stump became edematous and pus formed which necessitated an amputation in the course of the thigh. The blood was sterile and remained so. The author found the source of the peculiar behavior in a dissection of the amputated stump in which was a suppurative phlebitis. The wound proper had not been infected in the least, but this isolated infection of a vein had caused a bacteriemia and failure of the latter to destroy life or place it in peril is attributed to prompt extirpation of the focus. The report is very brief and the omission of any active chronology makes it more or less difficult to follow the author until at the end his summary makes the situation plain.

Correspondenz-Blatt für Schweizer Aerzte.

December 28, 1918.

Grippe at an Isolation Hospital Last Summer.—Wanner gives in detail a belated account of the epidemic which is usually of much more significance than the hurriedly published contemporary accounts. At Vevey 314 patients were cared for during a given period. Of this number 282 survived and 32 perished. The causes of death were as follows: bronchopneumonia, 27; pulmonary infarct, 2; cerebral type, 1; pneumonia followed by pyopneumothorax, 1; simple grippe (bronchitis), 1. The mortality was, as seen, 10 per cent.—somewhat less than at Basle, in which city it reached 15 per cent. Many interesting comments are made, such as the almost total absence of nasal sinusitis and otorrhea. Nosebleed, very common, had no clinical significance. About one-third of all victims showed some form or degree of pneumonia. The few cases of primary pneumonia appeared in the overworked. Unfortunately the author could make no autopsies and must depend on the finds of some of his colleagues. To sum up in brief, he would state that foci of bronchopneumonia supervene in a very insidious manner, in striking contrast with the brusqueness seen in measles and whooping cough. In the latter we see stitch in the side, rusty sputum, dyspnea, slight cyanosis, and an ascent in temperature and pulse with nasal dyspnea. These symptoms were practically lacking. Herpes febrilis was extremely rare. Auscultation gave unusual signs. Bronchopneumonia must always be sought at the extreme bases of the lungs, and at the posterior aspects. Only twice were evidences found of implication of the anterior portions of the lungs. The pneumonia therefore showed a hypostatic character. In many instances a small focus could be noted to increase in size. Pneumonia of the apices was found but a few times. The evolution of pneumonia showed a most bewildering variation, and migration and relapse were among the irregularities seen. The mortality from bronchopneumonia was unusually low—25 per cent.—which might have been due in part to diagnostic skill in recognizing even the very slight forms, but the author speaks of higher mortality having prevailed in general.

Book Reviews.

International Clinics. Edited by H. R. M. Landis, M.D. Vol. II. Twenty-eighth Series. 1918. Price, $10.00 per year. Philadelphia and London: J. B. Lippincott Company.

The material contained in this volume is unusually diversified. In the first section, on "Clinics," the following topics appear: "A General Consideration of Pancreatitis," by E. W. Archibald; "Focal Infection as a Cause of Keratitis and Irititis," E. V. L. Brown; "The Interpretation of Urea and Non-Protein Nitrogen Estimations in the Blood in Various Kidney Lesions," John H. Larkin and I. J. Levy; "Clinics at the Lying-In Hospital, New York; Presbyterian Hospital, Chicago; Boston City Hospital, and Massachusetts General Hospital." The second section, on "Medicine," contains two papers, one by C. H. Minor, on "The Psycological Handling of the Tuberculous Patient," and the other by J. E. Lind, on "The Early Diagnosis and Treatment of Syphilis of the Nervous System." Dr. Joseph S. Neff presents an article on "Babies and the Rising Cost of Milk," listed under the section of "Public Health." This is a timely subject in view of the high cost and scarcity of milk in some quarters at the present moment. Three contributions are found in the section on "Obstetrics and Gynecology," one of which is particularly worthy of note. This is entitled "Tuberculosis of the Vulva," written by C. Comberléran of Toulouse, France. He reviews the literature thoroughly and reports two cases of his own. Also from a French writer, Gaston E. Ayraud, is an article on "Primary Tuberculosis of the Conjunctiva," with report of a case, appearing in the section on "Ophthalmology." This is an extremely rare condition. In the domain of "Surgery" there are four presentations, as follows: "Gastric and Duodenal Ulcer," by M. H. Biggs; "Fulminating Appendicitis Complicated by Pneumonia," by G. S. Foster; "Fistula of the Rectum," by Charles J. Drueck; "Surgical Treatment of Exstrophy of the Bladder," by G. P. Müller. The final section, on "History," is given over to a syllabus on the important discoveries, inventions, and operations in obstetrics and gynecology, from the time of Hippocrates down to modern times, arranged in chronological and alphabetical order. Altogether we find this volume most stimulating and profitable reading.

A Compend of Genito-Urinary Diseases and Syphilis, Including Their Surgery and Treatment. By Charles S. Hirsch, M.D., Urologist to the Jewish Hospital and Mt. Sinai Hospital. Philadelphia. Third edition, revised. With 59 illustrations. Price, $1.50. Philadelphia: P. Blakiston's Son & Co.

In spite of such revision as the author has seen fit to bestow on this book, it still needs a thorough overhauling. Printers' errors, slipshod statements, misspelled words, and sentences which defy grammatical analysis are far too numerous. The pages containing the prescriptions with their curious combination of English and barbarous Latin, which formed one of the features of the previous editions, have been omitted; their elimination is, evidently, an easier task than their correction would have been. We would again suggest that this volume be revised and corrected.

Practical Physiological Chemistry. A Book Designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and of Science. By Philip B. Hawk, M.S., Ph.D., Professor of Physiological Chemistry and Toxicology in the Jefferson Medical College of Philadelphia. Sixth edition, revised and enlarged. With two full-page plates of absorption spectra in colors, four additional full-page color plates, and one hundred and eighty-five figures, of which twelve are in colors. Price, $3.50. Philadelphia: P. Blakiston's Son & Co.

For several years this work has been recognized as a standard. The new edition has been thoroughly revised and the author has brought it up to date. Among the new features we notice an important chapter on Acidosis; in this chapter the author gives a succinct review of the chemistry of the subject before proceeding to a consideration of the laboratory methods. The chapters on Metabolism, Blood Analysis, Gastric Digestion, the Quantitative Analysis of the Urine, and Growth have been enlarged. In two of the chapters the author has made important changes; these are the substitution of Van Slyke's method of determining the acetone bodies in the urine for all other methods, and the elimination of all methods for the quantitative estimation of urea, except those based upon the use of urease. These changes not only bring the book up to date, but also simplify matters for the student and laboratory worker. If only some fearless author or editor would eliminate 50 per cent. of the numerous tests given in every text-book, the gain would be enormous. The volume lies open at any page, and it has an adequate index. This sixth edition should be even more popular than its predecessors.

Dietetics for Nurses. By Fairfax T. Proudfit, Formerly Instructor in Dietetics in the Lucy Brinkley Hospital and Baptist Memorial Hospital, Memphis, Tennessee. Price $2.25. New York: The Macmillan Company, 1918.

The subject of Dietetics is of the first importance to the nurse, the physician and the patient. Unfortunately, until quite recently, most of the books on this topic which were available for nurses were little more than glorified "cook-books." At the present time, it is thoroughly understood that dietetics must be founded on a knowledge of Nutrition and Metabolism. Such is the basis of the present volume. The author wisely refrains from allowing the book to assume too scientific an aspect; but every chapter gives evidence of a proper scientific basis. A knowledge of dietetics presupposes an acquaintance with the food requirements of the individual, both qualitatively and quantitatively, in health and under abnormal conditions; it also includes a knowledge of the composition and the caloric value of the several foods. In the book before us all these subjects are clearly and thoroughly set forth; and sample diets, with plenty of variety whenever possible, are provided for almost every disease. Details concerning the preparation and serving of the various meals are also considered. Numerous tables, containing much information in condensed form, will be found throughout the volume; and to each chapter there is appended a summary of its contents. Nurses are to be congratulated on having such an admirable book, which is thoroughly practical and which is, at the same time, based on the latest scientific views. Many physicians, too, whose knowledge of dietetics is quite meager and whose views on the subject are correspondingly hazy, might study this volume with pleasure and profit. Proudfit's Dietetics is a work of more than ordinary value; its subject matter is well selected and well arranged; its style is pleasing and accurate; and a knowledge of its contents (on the part of nurses and physicians) will prove an undoubted blessing to many a patient.

Gun-Shot Fractures of the Extremities. By Joseph A. Blake, Lieutenant-Colonel, Medical Corps, U.S.A. Price 4 francs. Paris: Masson et Cie., 1918.

Dr. Blake is a pioneer in the treatment of fractures by suspension and it goes without saying that during the war, on account of his position, he has had almost illimitable opportunities for testing the value of mechanical treatment of fractures of the extremities. The different methods of applying such are given in detail and it may be said that he has brought the system to a state of perfection, hitherto unknown. The book contains numerous diagrams.

Johnson's Standard First Aid Manual. Suggestions for Prompt Aid to the Injured in Accidents and Emergencies. Edited by Fred B. Kilmer, Lecturer in First Aid; Member of St. John's Ambulance Association, the International Congress of First Aid and Life Saving, the American Public Health Association, etc., etc. In Collaboration with Eminent Surgeons, First Aid Authorities and Specialists. Illustrated. Eighth Edition Revised. New Brunswick, N. J.: Johnson and Johnson, 1918.

This is a good book on first aid and is got up and written in such a manner that it is easily comprehensible. Also, it is exactly what its title implies, a first aid book and nothing more. It does not go beyond its province, but gives information on first aid procedure succinctly and concisely. It is graphically illustrated.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held April 5, 1918.

Dr. SETH M. MILLIKEN IN THE CHAIR.

THE program of the meeting was furnished by the First Surgical Division of Fordham Hospital.

Subdural Hemorrhage, Osteoplastic Flap.—Dr. ANTHONY H. HARRIGAN presented this patient, a boy 8 years of age, admitted to the hospital on January 14, 1918, with a fracture of the skull. Dr. Harrigan said the child had been injured by a fall of about ten feet, and was picked up in an unconscious condition. He vomited twice, the vomiting being projectile in type. The pupils reacted well, the right being larger than the left. His pulse was 70 per minute; and respiration 30 per minute and rather "catchy." The right side of the parietal bone was tender and covered with hematoma. The muscles were more spastic on the right side. The reflexes showed exaggeration; Babinski was present. Examination by Dr. Byrne showed slight impairment of motion of left arm and left leg. The face was flattened on the left side but not paralyzed, though there was more movement on the right than on the left side. Sensation was impaired on the left side. After rest and sleep both pupils were equal and reacted to light and accommodation. On the following day the patient regained consciousness and his general condition improved. He had minor regular twitchings of the upper lip and right side, lasting five minutes. There were no signs of increased pressure and no signs of palsy. The urine contained sugar. On the second day the patient had a spell of weakness and the pulse rate varied. He reacted well to stimulating enema. There was a Babinski plantar reflex on the left side and a suggestion of such a reflex on the right. The child recognized his parents. On the next day he became very restless, lucid intervals shorter and fewer, respiration slower and somewhat labored. The patient continued in about this condition for several days, when he improved. The pathological examination of the spinal fluid at the time of the patient's admission showed a large amount of blood, but they were unable to make an accurate cell count or butyric acid reaction. At operation, on Jan. 14, 1918, a medium sized flap with the base in the temporal region was turned back. The superior border measured about four inches and was one inch from the sagital suture. Two trephine openings were made at each superior angle. The intervening bone was divided with a Di Vilbiss forceps. A linear fracture of the vault of the skull was seen immediately behind the posterior superior skin margin. The Di Vilbiss forceps grooved into this line of fracture, the fracture serving to complete the division of the bone flap, which was turned down. There was slight epidural hemorrhage, a few small black blood clots. The brain did not pulsate. It seemed under tension. A dural flap with the base above was formed. Considerable blood fluid escaped when the dura was divided. The exploring finger was placed downward to the base of the brain and the brain lifted up. This permitted a considerable amount of black cotted blood with brain tissue to flow out. A piece of bone was removed at the upper angle. The dural flap was not sutured. The bone flap was replaced and closed without drainage. This was a case of subdural hemorrhage with laceration of the brain. Drainage was not employed for fear of introducing infection. The brain appeared intensely congested, and had a dark color. The blood pressure estimates were taken every ten minutes during the operation; but very slight shock occurred. The patient was discharged on January 30, and had made a good recovery.

Case of Osteomyelitis of the Tibia.—Dr. ANTHONY H. HARRIGAN reported this case which occurred in a boy 15 years of age, who was admitted to the hospital with the history, that one week before, while coasting, he struck his left leg against a rock. He experienced some pain. A few days later marked swelling and redness appeared over the left leg. The patient was admitted to the hospital with the diagnosis of osteomyelitis of the tibia. Operation was immediately performed. A long incision was made over the inner surface of the shaft of the tibia. The periosteum was divided. An abscess was found between the periosteum and the cortex of the bone. The medulla of the bone was opened with the chisel; the medullary cavity was filled with pus. Subperiosteal resection of the shaft of the tibia was done, removing practically the entire shaft. The cavity left was packed with plain sterile gauze. The patient had a protracted convalescence but recovery ultimately took place with complete regeneration of the shaft of the bone. The patient now had a strong well-developed limb and could walk and run. A pure culture of staphylococcus was found.

Acute Osteomyelitis of the Femur.—Dr. ANTHONY H. HARRIGAN presented this patient, a boy eight years of age. He stated that the boy was admitted to the hospital on July 27, 1917, with the diagnosis of acute myelitis. One week previous to admission the child fell on the sidewalk striking his knee. There were no symptoms or signs for two days. On the third day after the injury he suffered pain about the knee and over the lower one-third of the femur. The pain increased, becoming boring in character, and the child became feverish and had a chill. His bowels were constipated. The child appeared acutely ill. His temperature was 105° F. The physical examination showed the tongue coated, pointed, and fissured, and slight congestion of the throat. All the second heart sounds ended suddenly and were accentuated; there were no murmurs. The right leg showed marked swelling around the right knee, extending some distance above and below. It was extremely painful on palpation. The reflexes were normal. An operation was performed on July 28, 1917. An incision was made on the outer aspect of the right thigh from the joint nearly up to the trochanter. The muscles were cut down to the bone. Pus was first found subperiosteally near the epiphysis of the knee. The periosteum was reflected and the bone chiselled away, thus opening up the medullary canal well from the epiphysis to the trochanter. The canal was curetted. The bone showed evidence of lesionism being friable and containing pus. A posterior moulded splint was applied. A second operation was performed on August 31, 1917, for cellulitis of the right leg. Pus was evacuated and gauze packing applied. On September 18, 1917, it was necessary to operate again for an abscess of the right leg. A small amount of granulation tissue was twice curetted out of the lower part of the shaft. The foot was forcibly flexed. A posterior moulded splint was applied. The *x*-ray showed osteomyelitis involving the entire shaft of the femur, and a series of *x*-rays taken at intervals after the operations showed gradual regeneration. There was no evidence of bony ankylosis. A culture taken from the bone at the time of the first operation showed the presence of the streptococcus together with a gram negative bacillus. The patient was discharged apparently entirely cured on February 10, 1918.

Birth Palsy (Erb's).—Dr. ALFRED S. TAYLOR presented this patient, a child 15 months of age, upon whom he had operated nine months previously, when the child was six months old. He employed the Sever operation which he described. He emphasized the importance of the postoperative care as a factor in the ultimate outcome following this operation. Attention was given to the details of the after treatment in this case and the functional results were extremely satisfactory.

Hemorrhagic Osteomyelitis of the Femur.—Dr. SAMUEL BOORSTEIN presented this patient. He stated that the work of Barrie had stimulated the surgeons and orthopedists to consider hemorrhagic osteomyelitis as a diagnosis when the patient gave a history of trauma followed by symptoms of myelitis, but not of an acute infectious type, and without fever. The radiogram showed a marked rarefied area in the end of the long bones which progressed rather rapidly. These cases used to be diagnosed as sarcoma of the bones and amputation of the limb was usually urged. Still many cases came under orthopedic observation where it was difficult to differentiate between hemorrhagic osteomyelitis and real sarcoma, and, of course, where an opportunity was offered to operate on the case and get the pathological

findings it should be reported. This patient, thirty-six years of age, came under the speaker's observation in November, 1917. His previous history was negative. His present illness began on October 3, 1917, six weeks, at which time he fell striking his hip. He had since complained of pain in the hip, which was worse at night and was aggravated by walking. In a week or two he began to limp. He was treated for rheumatism by electricity, etc., but no relief was obtained; on the other hand, he progressed worse all the time. Physical examination, on November 16, 1917, showed a marked limp to the right, slight limitation of flexion, adduction and abduction, marked limitation to inward rotation, and some limitation to outward rotation. There was marked tenderness over the great trochanter and some fullness over Scarpa's triangle. The measurements showed no shortening, but atrophy of 1 inch over the right thigh. The *x*-ray taken at this time showed marked bony atrophy involving the entire greater trochanter with definite evidence of cavity formation. The temporary diagnosis was hemorrhagic osteomyelitis. A second *x*-ray, taken six days after the first, showed evidence of rapid progress. The Wassermann was negative and the temperature normal. The patient was operated on, on November 22, by Dr. Nicoll and the speaker. The outer layer of bone was found very thin and brittle, almost ready to burst. The cavity was filled with a mass, grayish or white in color and thick in consistency. There were no bony structures. The walls of the cavity were of irregular outline and some bone bridges traversed the corners of the cavity. There was some oozing of blood. The contents were removed and the cavity well curetted. A drain was put in and a plaster cast applied. The microscopical report by Dr. Heitzman, the pathologist of the hospital, stated that the soft tissue as well as the periosteum showed pronounced congestion, with some hemorrhagic extravasation and inflammatory infiltration. The bone showed a considerable degree of softening and rarefication. The bone marrow was filled to a considerable degree with blood corpuscles, the hemorrhagic extravasation being pronounced. Inflammatory infiltration was everywhere marked and there was a conglomeration of leucocytes present. The diagnosis was hemorrhagic osteomyelitis with osteitis and periosteitis. The pain stopped two or three days after the operation, and the patient was permitted to walk on the cast two weeks later. The *x*-ray taken December 31 showed that the involved region had evidence of bone condensation, probably regeneration. A brace was ordered for the patient, which he wore at present. He has no pain at night, but he could not as yet put his full weight on the limb. A later *x*-ray showed beginning of regeneration of bone.

Chronic Pancreatitis with Fat Necrosis, Multiple Perforations of the Anterior Wall of the Stomach.—Dr. Louis Marton reported this case. He stated that the patient was forty-six years of age and a widow. She was first admitted to Fordham Hospital on November 7, 1917, on the service of Dr. Alexander Nicoll. Her family history was negative. Her present illness began seven days before her admission with constant pain in the epigastrium, radiating to the right shoulder. She vomited, was jaundiced, and had jaundiced sclera. The patient recalled a similar attack five years ago. The diagnosis was made of common duct obstruction. At the first operation by Dr. Alexander Nicoll a search for the gall bladder showed that it was buried in a mass of dense adhesions. After considerable burrowing dissection, a degenerated tit-like gall bladder was found with the common duct thickened and indurated; no stones were found. The head of the pancreas was much enlarged and nodular. The common duct was laid open and drained by two drains, one going toward the ampula and the other toward the hepatic duct. The drains were retained for several weeks and then they were spontaneously expelled. Upon discharge from the hospital her jaundice cleared up and the biliary sinuses closed. Nine weeks after the first operation the patient was brought in again with the diagnosis of ruptured gastric ulcer. Since leaving the hospital she had had pain on and off, associated with spells of vomiting, the character of which was not observed. On May 11 the pain became intense and the patient vomited material fecal in character. Upon admission and on physical examination typical boardlike rigidity of upper half of abdomen was present. At operation a plastic exudate presented which seemed to form a partition between the upper and lower portions of the abdomen. The stomach was found pulled over and adherent to the under surface of the liver. Upon inspection tremendous adhesions, almost the thickness of an index finger, were found extending from the pylorus and duodenum to the head of the pancreas, preventing the stomach from being delivered into the wound. The abdomen was walled off from the right upper quadrant, and as the stomach was peeled from the liver the speaker's finger passed into a hole in the stomach wall which upon first thought conveyed the impression of traumatic injury. However, as the peeling from the liver was continued, the anterior stomach wall was found to have undergone a digestive process. Its consistency in areas was the thickness of fine paper and as many as twenty perforations were encountered. These perforations were conical in form, the base corresponding to the serous coat, a sort of digestion from without inward. The patient's condition became alarming, so a hasty repair was decided upon. This was done by inverting the anterior wall of the stomach and burying this with a row of continuous Lembert sutures, producing a sort of hour-glass effect, and covering this with omentum. A number of white opaque areas were found which resembled fat necrosis of pancreatic digestion. The pancreas was found to be almost double the size it was at the former operation; in fact, so tense that the head and body were explored with an aspirating syringe, exploring for possible abscess or cyst formations. About a dozen points were punctured and aspiration yielded from 1 to 5 c.c. of thin turbid fluid. One cigarette was placed over the head of the pancreas and another toward the under surface of the liver. The abdomen was closed in the usual manner, using kangaroo tendon for reinforcement sutures in the fascia. The patient made an uneventful recovery. At the time she was operated on she weighed 120 pounds and at the present time weighed 180 pounds, having made this gain in eight months, being discharged from the hospital at the end of four weeks. The interesting feature, though puzzling, was to account for the enormous increased distention of the pancreas and recovery in the presence of fat necrosis.

Hemorrhagic Peritonitis. Two Cases.—Dr. Louis Marton presented these cases. He said that probably the name given to these cases was a misnomer, the term peritonitis meaning very little. The first patient was 30 years of age and had been treated for acute indigestion by one physician and for lumbago by another. On November 3, 1917, he had an acute attack of abdominal cramps and after expectant treatment went back to business, but was always uncomfortable. The present illness began with a sudden attack of pain and vomiting. The vomitus was sour. The pain was sharp, radiating to the left side of the back. The patient suffered from nausea and the bowels were loose. The pain became generalized and on physical examination the abdomen was found to be markedly distended but not the painful rigidity associated with a ruptured appendix. On opening the abdomen the peritoneum looked very bluish much as it did in a case of intestinal obstruction. The abdomen was filled with serous fluid and the condition looked very much like a case of acute intestinal obstruction. Finally the ileocecal junction was brought into the wound and the appendix delivered. The gallbladder was found to be full of small stones. A rapid cholecystectomy was done. There was nothing, however, to account for the exudate in the abdomen. After a long convalescence the patient made a good recovery. In the vicinity of the appendix there were areas of hemorrhagic extravasation and distinct inflammatory infiltration. He called attention to the pathologist's report of these small areas of hemorrhagic extravasation and to several distinct circular masses of hemorrhagic extravasation because the case report of hemorrhagic peritonitis was accounted for by finding these little hemorrhagic spots in the appendix. What relation or bearing they had on the cases he had not been able to determine.

Acute Cholecystitis in a Child Two and One-Half Years Old.—Dr. Louis Marton presented this case, a child 2½ years of age, admitted to Fordham Hospital about six weeks ago with the diagnosis of acute intus-

susception. On physical examination the typical sausage-like mass was found occupying the right hypochondriac and iliac region. The child had passed no blood by way of the rectum and that made one look for obstruction. What had been pointed out as visible peristalsis was found to be only the inspiratory and expiratory movements. On opening the abdomen there was no evidence of any gut distension anywhere but there was a tremendously distended gallbladder, the size of a gallbladder in an acute cholecystitis in an adult. It was filled with tarry bile. There was no evidence of any other lesion except marked stenosis of the cystic duct. The child was drained for about three weeks and then the tube was removed and the child seemed to be doing well, but developed bronchopneumonia which terminated fatally.

Operative Treatment of Epilepsy. Four Cases.—Dr. JOSEPH BYRNE presented these cases.

CASE I.—Dr. Byrne said that this patient, a girl 14 years of age, had been run over at the age of three years and was unconscious for quite a long time. At the age of eight years she began to have attacks of petit mal, numbering ten or twelve a day. She finally developed attacks of grand mal when the attacks of petit mal ceased, she had four or five grand mal attacks a day and later these became less frequent, being only two or three a week. She went along in this way until about a year and a half ago when she came under our observation. The usual examination of the spinal fluid and eye grounds, as well as *x*-ray of the head, etc., were made. It was decided on the basis of the signal symptoms that it would be best to operate on the left side of the skull. Since operation the girl was much better. Most of the cases reported on for epilepsy had a few grand mal attacks within the first few days after operation and then there might not be any attacks for a long period. This was what happened in this case. About six weeks after the operation the girl's father treated her rather harshly and she immediately had grand mal attacks. She was given bromides and suggestive therapy. She had thirteen attacks since operation one year ago but had improved most wonderfully in general health and mentality. The bromides were discontinued for long periods without recurrence of the attacks, but recently she had had another attack and she was now getting a small amount of bromides, in addition to treatment along the lines of mental therapy as suggested by Dr. Pierce Clark in the essential epilepsies. She was now attending school, and making satisfactory progress.

CASE II.—Dr. Byrne stated that this patient was a man 55 years of age, who had had many injuries of the skull. As a boy he had been kicked in the head by a horse and had had several accidents. About ten years ago he began to have epileptic seizures. One and a half years ago he had a stroke of apoplexy causing right hemiplegia. He recovered fairly well from this and had been in fairly good condition, still having, however, epileptiform seizures (grand mal) every four to six weeks. He was operated on and was greatly improved. Since the operation, left sub-temporal decompression one year ago, he had had no attacks with the exception of one four days ago. No bromide treatment was given since the operation

CASE III.—Dr. Byrne said that this man was now so well that he had been taken into the Army. He was a traveling salesman with a history of trauma. His attacks of grand mal began as sensory disturbances in the right hand, that was, a feeling of pins and needles or of an electric shock. It was worthy of note that pain was not a feature of cortical irritation. In all cases in which pain was complained of we should find out whether the patient meant the same thing when he spoke of pain as the physician meant. In many cases in which patients complained of so-called pain in the head it was found on analysis that he had no pain in the real sense of the word, but an abnormal feeling which caused alarm, which he called pain for the want of a more definite term. Irritation of the sensory cortex did not cause pain in the real sense, but a feeling of itching without disagreeable effect. Soon after the operation he had several grand mal attacks, but none since leaving the hospital. His attacks formerly came at intervals of one year or ten months apart, so in his case it was probably too soon to state definitely just what benefit he had received from the operation. His general condition was however markedly improved.

CASE IV.—This patient, a man 45 years of age, had a fall between his fourth and fifth year. He lost the faculty of speech and had some paralysis. The left eye now showed optic atrophy, which not rarely followed apparently trivial injuries of the orbit. The patient had formerly been able to attend to his business, but of late years he had been unable to hold a position. It seemed possible that in this case mental therapy had been a help as well as the operation. It sometimes seemed that the mere performance of an operation put the patient in such a state of expectancy that mental therapy could be used most effectively. Since operation this man had no attacks as long as he behaved himself, but if he imbibed too freely or ate intemperately an attack might supervene. Since the operation the patient's condition was so much improved that he got married. It seemed that his sexual power was somewhat impaired. Dr. Byrne said that Dr. Taylor would tell about the operations.

Dr. ALFRED S. TAYLOR said he was not prepared to give the details of the operation, but he would like to make a few remarks in reference to the conditions found in traumatic epilepsy. When the bone flap was turned down the dura was found to be more tense than normal, and there was practically always more or less infiltration of the arachnoid, which was opalescent rather than translucent, as it should be normally. The veins of the cortex were very much enlarged. The superficial layers of the cortex were rather more firm than they were normally. When one incised the superficial layers of the cortex there was soft brain tissue underneath. When one operated on an epileptic he laid himself open to criticism. It had been said that the idea that epilepsy could be benefited by operation was an exploded theory. Their experience in regard to operations on epileptics was that, while there were a few recurrences, in a fairly large percentage of cases the operation effected a cure. One man upon whom they had operated had remained free from seizures for ten years. Others had had no recurrence after five, six, and seven years. It might be said that a small percentage of epileptics, particularly those in whom the condition was caused by trauma, were completely cured; a much larger percentage were improved over a long period of time, and some few were not improved at all. However, as the operative procedure did not incur any risk to life and was a brief operation, it seemed that if a small percentage of cases could be cured and a larger percentage improved, even if the majority of cases did not turn out as well as one hoped, nevertheless performing the operation was not only justified but was demanded, because if these epileptics were not cured or improved they grew steadily worse and of less and less value to the community. Dr. Taylor stated that one of the patients presented had a hemiplegia in addition to epilepsy. In this case a right-sided subcortical decompression was done, and the patient made a good recovery and the spasticity was somewhat relieved. His observations had shown that the cases of hemiplegia that were very spastic had a great deal of brain lesion, and that the amount of brain lesion corresponded, as a rule, to the degree of spasticity.

The second patient, Dr. Taylor said, was a lady who had a hemiplegia following pneumonia; in other words, an embolic hemiplegia. She developed an early and severe spasticity. When she came to the hospital she was carefully examined by Dr. Byrne and it was decided to give her the advantage of an operation. A subcortical decompression was performed, removing a segment of bone about 2 to 3 cm. The dura was tense. It was split radially and the brain was exposed. A cystic degeneration of the cortex was found just above the fissure of Silvius. There was a soft cystic degeneration running up to the cortex. This wound healed by primary union and the patient was given postoperative orthopedic treatment. The speaker said there was one point to be emphasized and that was the choice of cases for operation in hemiplegia. It seemed to him that if one could get this marked improvement in cases of long standing, it was obvious that the best time for treatment was immediately after the hemiplegia had begun. In hemiplegia the operative risk was very slight. One exposed the area where the clot had formed

in the subcortical area, and if one slipped in a groove director the clot would exclude itself. The danger in the operation was twofold. There was the danger of the rupture of nerve fibers in the brain substance, and that was an injury that could not be repaired. If a clot persisted one would have continuous pressure on the surrounding nerve fibers which had not been ruptured, but which if exposed to continuous pressure would become degenerated, so that in order to preserve function it was important to relieve pressure. If one got a case in reasonably good condition, one could do the operation very satisfactorily with very slight risk and could turn the clot out of the brain with almost no danger to the brain substance itself, and one could get better results than by tentative treatment. It was possible to do the operation without any anesthetic, because the patient was unconscious and the operation was not painful. Dr. Taylor referred to several cases reported in the literature in which operation was performed for hemiplegia, and stated that he had one case in which he operated ten days after the hemiplegia began. This woman fell downstairs, was unconscious, and was found to have albumen in her urine. The *x*-ray did not show anything definite, so it was decided to explore her skull. This patient's breathing was stertorous. She was operated on and it was found that she did not have a fracture of the skull, but a clot beneath the cortex. At the end of two or three weeks she died, but not because of the operation but because of a chronic uremia.

Stöffel's Operation for Caisson Disease.—Dr. ALFRED S. TAYLOR and Dr. JOSEPH BYRNE presented this patient. Dr. Taylor stated that the patient had shown spastic paraplegia for over a year and had lately come to Fordham Hospital seeking relief from the spasticity. The obturator was cut and the spasticity was relieved somewhat. The man was now working, which he had not been able to do before this operation was performed. The Stöffel operation was a very simple procedure, consisting in making an incision in the groin and paralyzing the adductor by cutting the obturator nerve.

Tendon Transplantation in Anterior Poliomyelitis.—Dr. SAMUEL W. BOORSTEIN presented these four cases. He stated that though patients suffering from the effects of anterior poliomyelitis visited the orthopedists and were operated on by them, still the surgeons were often consulted about such procedures and it would probably be of interest to see the results of some operations. In fact, tendon transplantations were used in so many operations that the surgeons were as much interested in them as the orthopedists. All the patients to be shown were operated on two years ago, or at least one year ago, so that sufficient time had elapsed to note the improvement. He had used at that time the old methods of putting the tendon through the subcutaneous tissue. At present, stimulated by the studies of Biesalski and Mayer, he had passed the transplanted tendon through the sheath of the tendon to be replaced.

CASE I.—This child, eight years of age, had an attack of poliomyelitis when eighteen months old. He came to Fordham Hospital, in 1915, with marked contractures of the left knee and left tendo-Achilles. The foot was in the position of talipes equina valgus. The child was operated on in November, 1915, when the tendo-Achillis was lengthened and the foot corrected. The entire limb improved after that. On May 1, 1916, the biceps were transplanted for the quadriceps. The patient could walk fairly well using those muscles. Lying on the face, he could extend the leg, but against gravity he could extend it only partially.

CASE II.—This patient, ten years of age, became paralyed at the age of five, both lower extremities being affected. He was admitted to the hospital on April 11, 1916, with marked deformity of both feet and inability to walk. At operation, on April 15, 1916, an astragalectomy and tendon fixation of the peronei was done. The patient improved immensely after that. On April 27, 1916, the right foot was operated on and the contracted tendo-Achilles was split into halves anterior and posterior. The posterior half was lengthened by a "Z" incision and sutured. The anterior half was lengthened and transplanted into the cuboid. The peronei tendons were fixed in the fibula.

CASE III.—This patient, five years of age, came to the clinic on June 27, 1916. The trouble dated from the time she was one year old. The foot was in a position of talipes valgus. As the extensor hallucis was very active that muscle was transplanted to the scaphoid and the tibialis anticus was fixed in the tibia. The transplanted tendon was working very well, but it was not strong enough to hold the arch and the patient would probably need another operation. This patient was presented to show that it was not enough to transplant a muscle, but one must be sure that the transplanted muscle would be strong enough to take the work of the other muscle.

CASE IV.—This patient was six years of age and had had infantile paralysis five years ago. She was operated on last year, when an astragalectomy was done. The result was very satisfactory.

Peripheral Nerve Suture.—Dr. ALFRED TAYLOR and Dr. SAMUEL W. BOORSTEIN presented this patient. (See MEDICAL RECORD, January 5, 1918, page 11). He said that on October 15, 1914, this patient, a young student twenty-two years of age, while playing football, was thrown to the ground sustaining an injury to his left leg. The head of the fibula was pushed outward (dislocated laterally), but the tibia remained in place. The bone was replaced on the field, but the patient could not walk home. In a day or two the knee became swollen and tender, and he had to be confined to bed for five weeks. By that time the swelling and pain subsided and he began to walk, but he had foot drop and, as he expressed it, had no control over the movements of the toes and had very little sensation in them. Five months later he came to the orthopedic clinic of Fordham Hospital for relief of these symptoms. Physical examination showed paralysis of the peronei and tibialis groups. The extensors of the toes were completely paralyzed and there was marked atrophy of the calf and foot muscles. The *x*-ray picture, taken to determine the presence of fracture, was negative. A diagnosis of injury to the external popliteal nerve was made. Believing that the nerve was beginning to regenerate, conservative treatment by using a brace to prevent foot drop, massage, and exercise were resorted to for two months. No improvement resulted. An operation was then decided upon, which was performed on May 4, 1915. At the operation it was found that the nerve at the head of the fibula was embedded in a mass of fibrous tissue for a distance of 2 to 2½ cm. This 2½ cm. of the nerve was removed and an end to end anastomosis performed by carefully coapting the ends where good bundles were found and using a layer of fascia to prevent adhesions. Fine chromic catgut was used as suture material. The nerve was not freed for any longer distance. The knee was put in acute flexion to allow complete nerve union. The skin was united by first intention. The nerve tissue removed was examined by Dr. John H. Larkin, who reported that the mass consisted mainly of connective tissue. Few healthy fibers were present and there were only slight attempts at regeneration. Four weeks after the operation the speaker began stretching the knee gradually, placing it in plaster and changing this every week. The ankle was kept at right angles to prevent foot drop. At every sitting the knee was stretched until the patient asserted that there was a sensation of pain as if pricked by a needle. Two and one-half months after the operation the knee was straight and the brace was reapplied, allowing the patient to walk. At the same time electricity, massage and muscle training were ordered. Four months after the operation the patient could extend the four toes and flex the foot slightly dorsally. Six months after the operation there was increased motion in the tibialis anticus, but not in the peronei. Eleven months after the operation the patient was able to walk without the brace. He even played baseball. He could walk without a limp, but in running limped slightly. Twenty five months after the operation the motor power in the anterior and posterior tibial and peroneal groups had returned completely, though the very delicate tests of Dr. Byrne had shown slight weakness as compared with the sound side. Sensory functions showed more variations. This case demonstrated the value of early suturing of the nerve wherever there is a suspicion of injury to the nerve. If an injury was found it could be repaired. If no injury was found one had only a skin wound to close. The case demonstrated clearly the value of orthopedic treatment; the muscles must be kept in

proper position before the operation and afterward so that the denervated muscles did not stretch. This was a point very frequently neglected by the surgeons and an overstretched muscle would never recover.

Dr. JOSEPH NUTT asked Dr. Harrigan why it was that in the case of the tibia he made a subperiosteal resection, cleaning the bone out thoroughly, while in the case of osteomyelitis of the femur he simply removed the contents of the cavity and drained it. Why was this difference made in the procedure in the two cases?

Dr. HARRIGAN, in reply to Dr. Nutt's question, stated that he removed the entire shaft of the tibia because the fibula still remained to act as a splint for the leg. This prevented shortening and permitted the bone to regenerate without undue contracture of the muscles. In the femur, on the other hand, it would be almost impossible to prevent contracture of the thigh muscles after removal of the shaft of the femur. However, Dr. Harrigan stated that he had removed the shaft of the femur in two cases. In the first case the patient died as the result of sepsis; in the second case the patient was removed from the hospital by his parents and the patient was lost track of. From a practical point of view, it was impossible to remove the shaft of the femur because the plaster of paris cast applied to hold the limb in its proper length quickly became soiled with pus, and had to be removed so frequently as to be valueless as a splint.

Dr. NUTT asked Dr. Byrne whether they operated on cases of epilepsy that did not give a clear history of trauma.

Dr. BYRNE replied that they did and frequently with favorable results.

Dr. BYRNE said he had studied all these cases with Drs. Taylor and Boorstein and they had recently presented and discussed a number of them before the Neurological Society. He would like to emphasize one point with reference to intracerebral hemorrhage of arterial origin. In this condition the moment the blood escaped from the artery the pressure exerted at the site of extravasation represented at least a pressure of 120 mm. of mercury and sometimes a much greater pressure. This pressure comes into competition with the much lower capillary blood-pressure in the surrounding tissues and the result was strangulation of the latter. We had, therefore, even in the case of a very small clot, a larger surrounding area of strangulated tissue which might be readily relieved by simple puncture of the cerebral cortex and the spontaneous extrusion of a small amount of clot or serum. In cases of embolism and thrombosis there were strangulated areas of greater or less extent surrounding the embolized or thrombosed end arteries in the region of the basal ganglion and internal capsule. In these areas reactionary processes of an inflammatory nature took place and very little in the way of exudate or secretion following cystic formation would suffice to so increase the local extravascular tension that the necessary interchange between neural tissues and nutritive media would be an impossibility. There were no true lymphatics in the central nervous system (Sabin) and the exact mechanism of the circulation in the neural tissue was, as yet, but little understood. It was certain, however, that in no region did elements of mesoblastic origin such as blood corpuscles come into direct contact with the neural elements which were of epiblastic origin. The perivascular spaces which took the place of the true lymphatics undoubtedly played an important rôle in neural nutrition as did the neuroglia which was itself derived from the epithelium lining of the neural tube and in intimate relation, on the one hand, with the perivascular spaces and, on the other, with the true neural elements. It will be readily seen that in cases of thrombosis and embolism of end arteries the removal of even a minute amount of exudate or secretion by cortical puncture might be the determining factor in re-establishing circulatory flow and metabolic interchange in certain small but extremely important functional areas such as those encountered in the vicinity of the internal capsule and centro-lateral aspect of the thalamus where, because of the condensation of nerve paths, a minute lesion might have permanent and widely extending paralytic effects. It was of interest to compare with this the rapid disappearance of large amounts of pleuritic exudate after exploratory puncture and the removal of a few c.c.'s of fluid.

Intradural and Extramedullary Sarcoma of the Spinal Cord with Paraplegia of Ten Years' Duration.—Dr. JOSEPH BYRNE presented a specimen which he said was three-fourths the natural size of the tumor. The patient from whom it was removed was thirty-eight years of age. Ten years previously she had had a pain in the area of the distribution of the twelfth thoracic and the first lumbar nerves on the left side. Later the left lower limb lost power. Three years before operation she lost the use of the right leg and presented the picture of paraplegia in extension. During the ten years of her illness she had given birth to three healthy children. The case was presented as a beautiful illustration of localization. By means of careful sensory tests they had been able to localize the tumor on the left side pressing on the pyramidal and spinalthalamic tracts and on the left posterior funiculus.

Dr. ALFRED S. TAYLOR said he did not remember all the details of the operation, but they did a left sided laminectomy and found the tumor lying beneath the dura, but not involving the cord. They had been able to enucleate it without doing a double laminectomy and without danger of damaging the cord. The patient unfortunately was the victim of a mitral stenosis and died suddenly a few days after the operation.

SECTION ON MEDICINE.

Stated Meeting, Held December 17, 1918.

DR. EDMUND P. SHELBY IN THE CHAIR.

Bacteriology of Influenza.—Dr. WILLIAM HALLOCK PARK gave an informal talk on this subject in which he said that we knew little about the etiology of influenza. It was fair to assume, however, that the epidemic was due to a single germ, just as we assumed that measles or poliomyelitis was due to a single germ. It was also fair to assume that the germ causing the epidemic throughout the country was a single strain. This assumption was warranted from the fact that the disease starting in this country in the East could be traced as an entity as it spread through the Middle West and to the Pacific Coast and Alaska. There was no question that some single virus spread through the country, though the disease produced may have been complicated in different ways and degrees by other organisms in different portions of the country. In the Eastern States the *B. influenzae* was the organism which was first considered as a possible causative agent. It had been suggested that this epidemic was a repetition of the epidemic of 1889-90, but it might be recalled that Pfeifler did not find the influenza bacillus until two years after the beginning of that epidemic. The first cases studied bacteriologically were in the neighborhood of Boston, at the Chelsea Camp. The *B. influenzae* was found by Keegan in 25 per cent. of these cases to be the only variety of bacteria that grew in cultures made from the lungs. This organism was found present in large or small numbers in practically 100 per cent. In a large number of cases there was found also the pneumococcus or the streptococcus, but the *B. influenzæ* was present in all cases. In New York we had under observation cases from various localities, from Europe and from Boston as well as from New York City. In the first group of 200 cases examined Dr. Anna Williams found the influenza bacillus in 80 per cent., and later she found them in 98 per cent. of the cases examined. It has been the experience of all that the more one works with the influenza bacillus the more likely one was to find it. One hospital reported that they were not finding any influenza bacillus; Dr. Williams examined the same group of cases and found in all the *B. influenzæ* in large numbers. The results obtained by men like Rosenow and Jordan, who did not find the influenza bacilli, made it necessary to recognize that the *B. influenzæ* seemed to be present more constantly in some parts of the country than in others and also differed at times in the same locality. Of twelve rabbits, each injected with a single strain of influenza bacilli from different fatal cases, every one made a serum which would agglutinate only

its own strain and therefore they had from twelve different cases twelve different influenza cultures. In view of such experiences as this anyone working in the bacteriology of influenza would find his doubts increasing week by week as to the etiology of influenza. Nowhere had they found the streptococcus, pneumococcus, or any other organism with regularity, and furthermore the streptococcus and pneumococcus were divided into immunological groups and the causative factor must be one strain. It was therefore their belief that influenza was due to an unknown organism, possibly a filterable virus, but this supposition lacked evidence. The epidemic of 1889 and '90 was not any more certainly due to the influenza bacillus than the present epidemic. If we did not know the true cause of this epidemic it was difficult to believe that we could stop the epidemic by a vaccine. In New York a vaccine from mixed strains of influenza bacilli was used. It was evident that if one gave three billion organisms composed of twelve different strains that there would be a very small number of any one strain, not sufficient to produce a marked immunological response. Protection might be afforded against complicating organisms where these were of a definite strain as, for instance, one might vaccinate against pneumonia due to Type I and Type II, but this could afford no protection against Type IV. If one simply asked a physician who dealt with a large number of cases what his results were with the vaccines, he would probably tell you that they were good, but if there was a control group of individuals it was usually found that there was nothing or little in their favor. Dr. McCoy's experience was interesting in that the conditions for his experiment were ideal. The persons vaccinated were inmates of a State institution and the outbreak of influenza did not appear until three weeks after the vaccination. When the disease appeared in the institution there were more cases of influenza among the vaccinated than among the non-vaccinated. Dr. Rosenow was for a time perfectly sure that his vaccine made of streptococci, pneumococci, and influenza bacilli was the correct one, but after more extensive experience he had now decided that it must be adjusted to the bacterial flora of each locality. This made it not practicable. If one reviewed the experience of other investigators and hospitals in which groups of vaccinated and non-vaccinated individuals were compared it would be found that where good results had been obtained the vaccination had been done after the apex of the epidemic was passed. In other words, if you vaccinated after the epidemic had passed the apex you would have brilliant results, but in the very beginning of the epidemic the results would not be good. It was most discouraging to have to admit that we had found no germ that could be considered to be the causative agent in influenza and that there was no efficient vaccine or serum. If the virus was a filterable one and therefore probably not visible we were as helpless as we were before measles, and if complications were superimposed on an infection of unknown type it was evident that the problem became very complicated.

Tissue Emphysema in Influenza.—Dr. JESSE G. M. BULLOWA presented an account of seven patients suffering from tissue emphysema as a complication of influenza bronchopneumonia occurring in the Willard Parker and Kingston Avenue Hospitals. There were autopsy reports on two of the cases and two recoveries. In one of the recovered cases the tissue emphysema presented under the skin covering the tenth, the eleventh, and the twelfth ribs. In the others there was a marked emphysema at the root of the neck and over the first and second ribs. In one of the autopsied cases one lobe of the liver was honeycombed with air. Dr. Bullowa thought that the mechanism involved was the overstretching of the lung parenchyma to fill the chest cavity. Some of the parenchyma was over-stretched because of the large amount of inexpansile tissue due to congestion and inflammation. The conditions favoring the emphysema were met by hypodermic injections of adrenalin to diminish congestion, by reduction of the negative pressure of the pleura, by compression and fixation of the chest with adhesive plaster, or by the creation of partial pneumothorax induced in his recovered case by tearing the visceral pleura with an aspirating needle.

The Symptomatology of Influenza.—Dr. WILLIAM R. WILLIAMS presented this phase of the subject. He stated that this disease had been pretty thoroughly treated in the literature. Dr. Delafield seemed to have known this disease in most of its varieties and it had been described in standard works also on the basis of observations made in earlier epidemics. It might be not without interest to speak of some of the manifestations of the disease as they were met in this epidemic and of some of the more frequent complications. We did not know what to designate complications and what the disease. Pneumonia was so frequent that it did not seem right to call it a complication. Very few cases ran a fever for several days without having a certain amount of pneumonia as a part of the condition. Cases observed with the *x*-ray showed early in the disease a shadow reaching out from the root of the lung, which was not that of a normal lung; some of these patients later had a definite consolidation and pneumonia. On the Second Division of the New York Hospital they had had 230 cases, exclusive of those now in the hospital. Among these there were 29 in whom there was a failure to make out the clinical signs of pneumonia; all the others showed signs of consolidation. Of the cases without pneumonia none died. Of the entire series the mortality was 30.4 per cent. Fourteen of the patients died before they were in the hospital for more than a day. Among the more interesting complications were those associated with pregnancy, and this had been found a very grave association since most of the cases aborted without regard to the period of pregnancy in which the disease occurred and almost all of these pregnant women died. Dr. Williams said he was very much impressed by the appalling mortality of severe attacks of influenza in pregnant women. Some cases of heart disease stood influenza very well, even some of those with a history of more or less decompensation. There were four well marked cases of valvular disease, two of which went through the disease quite well and recovered and two died; these were bronchopneumonias with valvular disease of the heart. In chronic nephritis the disease was not as severe as might have been expected; the cases coming to autopsy, however, showed marked kidney congestion; others with chronic nephritis were only moderately worse than those with healthy kidneys. The empyema cases did pretty well and they had not been in a hurry to operate on these cases. They had used the *x*-ray to a considerable extent, having most of the cases with doubtful pleural signs radiographed. The signs had been most deceptive, but if one watched them for a few days the diagnosis could be made. It seemed to him that never before had he seen so many cases with puzzling signs as to whether or not liquid existed in the chest, and they had almost given up the idea of diagnosing the presence of liquid by a single examination. If these cases were examined on successive days one would begin to note râles and resonance. They had found some cases with ordinary phlebitis of the veins of the extremities and if these were confined in bed they did well. They had had some cases with very striking meningeal symptoms in which, if influenza had not been present, they would have been confident that the patients had meningitis. The examination of the spinal fluid and the outcome in these cases convinced them that the patients never had meningitis. They had also had one case strikingly suggestive of tetanus, with tonic spasms of the limbs; the spinal fluid, however, was quite negative, and these symptoms disappeared with defervescence. With reference to the duration of the fever, in the milder cases the fever was of from three to five days' duration. On the other hand he had had a patient who ran a fever for 37 days and in others it had lasted quite as long. There were two types of fever, either a fairly even type or one that was extremely remittent, where the daily minimum might be normal and the maximum from 104° to 105° F. Occasionally patients shot up a temperature during convalescence. They had been unable to find a cause for most of these rises. The disease as most fatal seemed to be somewhat as follows: There were 33 cases under 16 years of age in which they had had no deaths, though since that time they had had two deaths in babies. In the next decade the mortality was about 28 per cent.; from 30 to 40 it was 39 per cent.; from 40 to

50, 35 per cent.; from 50 to 60, 52 per cent. The mortality seemed to be pretty much the same in the third, fourth and fifth decades. There was a much greater number of cases among the earlier decades than in the later. A most striking thing in connection with this disease was the wonderful congestion which existed of which one saw the evidence before death and at autopsy. This congestion seemed to strike everywhere. The patient might vomit blood; there might be a hemorrhagic condition of the gastrointestinal tract; blood in the stools, sometimes in considerable quantities, and congestion of the uterus as demonstrated by profuse menstruation and by abortion, and there was an enormous amount of blood in the lungs at autopsy. If we picked out any one point for emphasis it would be this congestion, which was so overwhelming in the cases of this epidemic seen this winter. It caused epistaxis, hematemesis, blood in the stools, and at autopsy there was hemorrhage in the mucous membrane of the stomach and bowels. There often was blood in the urine. The skin was much congested and cyanotic. Hemoptysis was common. Women who were not pregnant, menstruated; those who were pregnant aborted. Jaundice also occurred as a complication.

Dr. E. LIBMAN stated that, in the first place, as regarded pneumonia in this epidemic there had been the greatest diversity of type, the pneumonias having varied from the most virulent to the mildest ever seen in previous years. The pneumonias were very severe in the early part of the epidemic, being characterized by rapid onset, early general congestion, watery, bloody sputum, high fever, and then there was apt to be a false crisis with a partial drop in the temperature which was likely to deceive the physician. The patient, after an apparent improvement, would then have a smaller pulse and then the rate would become somewhat rapid and the temperature would become high and the patient was almost sure to die. The type of cases varied all the way from cases of this type to the very mildest cases. Whenever one got a case with moist râles he should be guarded in making a prognosis and this had been true of the cases seen during the past few weeks. A patient might do well for several days and exhibit signs only on one side of the chest and then the other side would become involved and the patient would become rapidly worse. Unless the patient had simply a few dry râles one must be very guarded as to prognosis. If at the time of the crisis one heard gurgling râles, even though the temperature was not high, the prognosis was bad. Dr. Bullowa had reported interesting cases of emphysema. Emphysema was due to two causes, rupture of the sub-pleural emphysema, or rupture of a small abscess on the surface of the lung, causing a pneumothorax or emphysema. There was an interesting relationship with tuberculosis. One got cases of influenza in which there was persistent cough and one had to be on watch for tuberculosis. One should examine not only the involved portion of the lungs, but also the apices, especially if the patient kept on running a temperature. On the other hand, an influenza pneumonia could occur in an area in which there had been a quiescent tuberculosis. An examination of the sputum should be made to be sure that tuberculosis had not spread into the seat of the pneumonia. As to the inexplicable rises in temperature—they might at times mean resorption fever due to the products of autolysis of the involved lung. They were now getting pleural complications which in the beginning of the epidemic were almost absent. The presence of diaphragmatic pleurisy might be indicated by sensitiveness of the trapezius muscle. Pain referred to the back of the neck and also some pain on swallowing, and temperature and cough might indicate that a focus was developing near the mediastinum. In one case the physical signs appeared near the spine after ten days of fever, cough, pain in swallowing, and pain in the neck. There were many complicating streptococcus pneumonias in the camps last year, which were contagious in character. Pleuritic effusions might be mistaken for pneumonia, but attention to the apex beat would serve to make the distinction. Sacculated empyemas seemed to be common during the influenza epidemic, but whether they were more common or whether one saw more of them because one saw more cases he could not say. If the apex beat was displaced and if the signs remained absolutely stationary for two to three weeks one might feel confident that there was an effusion and not pneumonia, as pneumonia did not remain stationary for two or three weeks. Sacculations might occur in the interlobar fissure and these gave signs higher in the axilla than behind. If one found flatness and the patient kept on having an elevation of temperature one should search the interlobar fissure (which ran across the scapula) for effusion located under the scapula. One should make a distinction between polynuclear fluid and pus; the latter were the cases to be operated upon. It was the rule not to operate unless real pus was present. If there was an odor the patient should be operated on at once. Dr. Libman also mentioned that he had seen eight cases in which there appeared to have been an infarction in a previously consolidated area. He also referred to the cases of embolism and of thrombosis due to arteritis.

Dr. MAURICE FISHBERG said that all were interested in the pointed remarks made by Dr. Bullowa on complicating cutaneous emphysema. He saw this condition very frequently in cases in which pneumothorax was induced for therapeutic purposes. In most instances cutaneous emphysema was hardly felt by the patient; in some it was an annoying symptom, while in all it was decidedly harmless. All recovered within a few days, or a week, the gas being absorbed during this period. The outlook when this complication occurred in influenza pneumonia was therefore good, unless the other symptoms were menacing. As to the suggestion to induce a partial pneumothorax, Dr. Fishberg could not see clearly any good to be expected. In his experience with artificial pneumothorax, which had been quite extensive, he had arrived at the conclusion that one could not be sure that an attempt at collapsing the lung would result invariably only in a small pouch of gas in the pleura. At times one punctured the parietal pleura, and injected a few hundred c.c. of gas, believing that only a partial pneumothorax had been induced, while an examination a few hours later revealed complete collapse of the lung—a complete pneumothorax. Of course, in such cases the visceral pleura had been punctured and a leakage of air from the lung had occurred. It was thus obvious that attempts at induction of partial pneumothorax in both sides of the chest might prove disastrous. In respect to the influence of influenza on the origin, course, and termination of pulmonary tuberculosis, Dr. Fishberg said that his observations during the present epidemic led him to the conclusion that, excepting in very progressive cases of tuberculosis, influenza had no influence on this latter disease. At the Montefiore Hospital, there was an epidemic of influenza in which most of the patients in one ward were affected. The temperature rose in the affected patients, the symptoms of influenza were all present, but within a week or ten days there was, in most cases, an abrupt ending by crisis; in some, by lysis. The physical signs in the chest remained the same as they were before the complicating disease made its appearance. In but few of active cases was there noted a tendency to progression as a result of the influenza, and but two patients, in whom tuberculous process was progressive and extensive, succumbed. These patients were hopeless cases, but the influenza accelerated them to the inevitable. Observations in his private practice also led Dr. Fishberg to the conviction that influenza had no particular tendency to reactivate latent tuberculous processes. He now saw in his office many pulmonary lesions which had remained as sequelæ after influenza, but they were not tuberculous. Their localization was mostly in the lower lobes of the lung where impairment of resonance, bronchial breathing, and large, moist consonating râles might be heard. But no tubercle bacilli were found in the sputum. In those in whom tuberculous lesions were discovered after influenza, he was able to elicit a history of tuberculous disease before the occurrence of the complicating influenza. It was Dr. Fishberg's opinion that no increase in the incidence of tuberculosis was to be expected as a result of the present winter's epidemic of influenza.

Dr. GEDIDE A. FRIEDMAN said he would like to ask the gentlemen whether really influenza was a disease which affected primarily the respiratory tract. He did

not believe it was because we had a clear nervous type and a clear gastrointestinal type of the disease. As an internist he had seen many cases during the epidemic of a purely gastrointestinal type in which there were absolutely no changes in the chest, and this had brought him to ask whether influenza might not be transmitted through an insect. Until ten years ago everyone considered typhus fever just as we did influenza to-day. However, it was found that typhus fever was transmitted through the body louse and we had had a similar misconception about the Rocky Mountain spotted fever until it was shown to be transmitted by the bite of certain ticks. He asked therefore if it was not possible that influenza was transmitted through an insect, not the louse, or the tick, but the bedbug. His reason for believing this was that the bedbug was everywhere, and had access to both the rich and the poor. Such an insect was in accord with the chief features of the epidemic. The insect must be in accord with the duration of time of the epidemic, that was the virus must be retained six or eight weeks, corresponding to the duration of the acute stage of the epidemic. The bubonic plague was spread in this way by the rat flea, but also by the bedbug, which retained the plague virus 48 days. Dr. Friedman cited several specific instances that lent support to his theory, and declared that he believed that on investigation influenza would assume the same aspect as typhus fever and other diseases, and that if the organism was demonstrated it would be found that there was an insect carrier.

Dr. L. T. Le Wald stated that he had been following some of these cases of influenza and pneumonia with radiographic examinations, and, as Dr. Williams said, there was difficulty in telling whether a collection of fluid was present. It was easy in many cases to tell whether fluid was present or not, but in some it was almost impossible to make a differential diagnosis; one could see a less dense area between the hilum and the diaphragm at times when fluid was absent, which was not there when fluid was present.

Dr. Park, in closing, said it was easy to bring oneself to believe in theories that had little basis in actual fact. As an instance it might be recalled that there was a few years ago a very interesting discussion on the question of poliomyelitis being produced by the rat, and some investigators succeeded in convincing themselves that they had proved this to be the case. As for influenza there were instances that seemed to demonstrate that it was conveyed by direct transmission, as, for example, a man went from his home where there was influenza, to the post office, and within 48 hours several persons with whom he had talked came down with the disease, or a person went from a house where there was influenza to school, and feeling ill, returned home, and within a few days many children came down with the disease. There were so many similar occurrences that there seemed to be no doubt that the disease was conveyed by direct transmission like measles rather than by a parasite. He had received a report from Dr. Irving on his work at Roosevelt Hospital. The nurses had been vaccinated from day to day and quite a number who were exposed came down with influenza before the vaccinations were done, so it seemed that the vaccinated were rather an immune group. There was very little to prove that vaccination did any good. As to quarantine, the evidence seemed to show that goods did not carry the disease, and that fact was additional evidence against the bedbug theory. It seemed that there was some contagion which was probably transmitted by carriers, probably by both the light and the very severe cases in the early part of the illness.

Dr. Bullowa, in closing, said he had probably not made it clear in his report that the cases had no pneumothorax but subcutaneous emphysema and that he had produced a partial pneumothorax. Dr. Fishberg had spoken absolutely of the emphysema that he saw in tuberculosis, but the emphysema in influenza was an entirely different condition. There was nothing in the mechanism of pneumothorax as produced in tuberculosis like that described in the paper. It was difficult to obtain a partial pneumothorax with the Forlanini apparatus, but with the W. Larry Morgan apparatus partial pneumothorax was a safe procedure, which the speaker had carried out successfully several times.

Miscellany.

Constipation as a Problem in Argentina.—The September-October number of the *Revista de la Asociacion Medica Argentina* is entirely devoted to the papers read before an extraordinary session of the Association on the subject of constipation. After President Lavalle had opened the session Mendez read a brief paper on spastic constipation. The treatment of this condition begins with the stomach and is essentially dietetic and the author upholds a diet rich in fresh meat with exclusion of cereals save as broths. The patient should manage to have several stools daily, preferably one after each meal. Castor oil, vaseline, and agar are useful with belladonna as an antispastic. These measures are to be used only over short periods of time as cure or great improvement is expected to follow. Escalier considers briefly the subject of constipation as an entity and subdivides it into groups. President Lavalle covered the subject of the surgical treatment of constipation based chiefly on the teachings and practice of Lane and Lynch. Udaondo discussed the etiopathogenetic factors and alluded first to the great service of the *x*-rays in throwing light on the different factors. We have learned the great frequency of spastic constipation but no longer regard the latter as a disease entity, for it must be viewed as a symptom. We must still find the causes which make possible this spasticity in the given case. When we further bear in mind that atonic constipation is likewise no unity but a symptomatic state, we realize the difficulty at times of making sharp distinctions and often the two expressions of constipation seem identical in etiology. They may alternate and even coexist. Stomach chemistry shows that the great majority of the constipated have hyperchlorhydria. The spastic and atonic states of the intestines are reflected in the similar behavior of the stomach. Constipation of rectal origin is now added to the longer known forms. Novaro discusses certain factors of constipation, as ptosis and colonic disease. He quotes largely from American surgeons with accounts of Jackson's pericolitis and similar conditions which form adhesions. Bosch Arana discusses the surgical management of these cases and of megacolon, and illustrates his articles with numerous original drawings. A number of case histories are added. This paper is much the most significant and original of the session.

Epidemics in Germany in the Fall of 1918.—The official report in the *Office International d'Hygiène Publique* for November shows that the incidence of certain epidemics in Germany has been much exaggerated. Cholera had claimed in all but 17 sufferers up to October 5. Typhus from July 28 to October 19 claimed about 23 victims. Variola from August 4 to October 12 had 10 victims. On the other hand the deaths from dysentery have been very numerous—from August 4 to October 12 nearly 2,000. The impression that food shortage is causing famine typhus is thus efficiently dispelled. Dysentery seems practically confined to Prussia, hence can scarcely be due to any great extent to food shortage.

THE MAJOR GENERAL OF DEATH.

BY CHARLES NAHUM HASKELL, M.D.,

BRIDGEPORT, CONN.

PNEUMONIA has long been the cause of more deaths than has any other disease, and it is, therefore, the most formidable foe with which we have to contend. In the past it has been referred to as the Captain of Death, but now that it has allied itself with influenza and various strains of cocci of bad repute it would seem to have earned the title of Major General.

As a result of my own experience, and the privilege of a goodly number of indirect observations, I am prompted to ask if we are all doing all that can be done in all cases of pneumonia that are entrusted to our care? Personally, I have experienced a degree of skepticism and discouragement in attacking pneumonia, and I find that this attitude is more or less prevalent in the medical profession. I am taking the liberty to make these general comments for the definite purpose of calling particular attention to some recent publications which present to us certain facts which would seem to point the way to more specific therapy in pneumonia, and I am not speaking with any pretense of special knowledge or experience.

I am assuming that under stress of professional demands, such as we have experienced in the past few months, many of us have overlooked some of the more technical reports with which we have been generously supplied in recent literature, and much of it, I am sure, would have escaped my attention had it not been for the alertness of my professional friends and associates, and my personal observations would have been limited but for their courtesy.

The more recent successes in the treatment of pneumonia have been due largely to the all important and absolutely indispensable cooperation of clinician and pathologist, and I cannot too strongly emphasize the fact. The clinician, however, is the first to come in contact with the patient, and therefore the burden of responsibility rests upon his shoulders.

It seems to me that the successful treatment of pneumonia depends to a considerable degree upon two things: first, its early recognition; and second, its prompt treatment. I am not unmindful of two other prime factors, namely, the virulence of the infection and the sort of patient with whom the disease has to deal.

It is not my purpose to dissertate on the diagnosis and treatment of pneumonia in a general way, for such material may be found in text books, but I wish to speak of certain facts relating thereto that are not generally taken into account and of some methods that are not universally practiced.

In the first place, I think that a patient in whom a diagnosis of pneumonia seems in any way probable should be visited and carefully examined at least two or three times a day, especially when the constitutional symptoms outweigh the physical findings. The fact that in many cases the symptoms of lung consolidation, as determined by percussion and auscultation, are very late in appearing, and occasionally do not manifest themselves at all, should always be kept in mind. It is best to be guided by the temperature, pulse, respiration, history of chill, cough, pain, and expectoration, and when a sufficient number of these symptoms present themselves pneumonia should at least be suspected. This suspicion should be the signal for prompt action, and the first step in the treatment of pneumonia is to control the heart action by the administration of adequate and effectual doses of digitalis tincture (fat free), and this should be done early and irrespective of the type of pneumonia in hand.

In cases of influenza pneumonia the pulse is often relatively slow, many times under a hundred, even though the temperature is abnormally high, and this is, in all probability, due to either an increase in the cerebrospinal fluid, with consequent increase of intracranial pressure, or a toxic irritation of the vagus nerve. This gives a sense of false security as to the strength of the heart, which should be guarded against; but it does not in any way contraindicate the administration of digitalis; and furthermore, heart lesions are no contraindication. The most approved method of administering digitalis tincture is that devised by Eggleston, and it has been rather universally used in the army camps during the past few months. The method, briefly outlined, is as follows: Multiply number of pounds in the patient's body weight by two, and give that number of drops of digitalis tincture within twelve hours. The amount should be divided into three doses, the first dose representing half the total quantity, the second dose half the first, given at the end of six hours, and the remainder six hours later. The remedy may then be discontinued for 48 or 72 hours and repeated or resumed in smaller doses according to the conditions present and the judgment of the physician. The stomach is not more frequently disturbed than with smaller doses, and when it is it readjusts itself quite promptly. By this method the heart is rapidly gotten into

condition to withstand the probable impending strain.

Simultaneously with the administration of digitalis a partial blood examination should be made; that is to say, a total and differential estimation of the white cells. In the presence of the influenza epidemic this procedure should at least help to differentiate between a post-influenzal type of pneumonia and a lobar pneumonia, and considering the fact that these two types must be dealt with separately, so far as treatment is concerned, this distinction is quite important. Practically all scientific workers depend largely upon this blood examination to distinguish these two types of pneumonia. The total white cell count runs abnormally low in post-influenzal pneumonia and correspondingly high in lobar pneumonia. I have seen the number of white cells drop to 2,000 and under per c.mg. in influenzal pneumonia, while 20,000 to 50,000 is common in lobar pneumonia. Differentially, the polynuclears are much increased in lobar pneumonia, while in post-influenzal pneumonia they are only moderately increased, and in some cases diminished. If the white cell count is abnormally high (normal 8,000 or 9,000), and the history and clinical findings seem to suggest the presence of lobar pneumonia, the sputum, if there is any to be had, should be sent to a laboratory for the purpose of determining the type of pneumonia with which one has to deal. Pneumonias, as we know, are classified by types, which are designated as Type I, II, III, and IV, and it is of some prognostic and therapeutic advantage to place each case in its proper class. On the other hand, if the white cell count is considerably lower than almost any acute infection would warrant, and especially if it be below the physiological normal, typing seems unnecessary, for one is dealing then with an influenza plus a mixed infection and possibly an unknown type of pneumonia.

Then, again, a total and differential white cell count is of some prognostic value, as pointed out some years ago by Sondern. A high total means good resistance on the part of the patient and a high polynuclear content indicates severe infection. Conversely, low counts mean the reverse.

In the light of present knowledge on the subject it would seem that every case of lobar pneumonia should, in addition to the generally practised methods, be treated with antipneumococcus serum. The literature for the past year or more has been replete with reports from most reliable sources, and they should receive our earnest consideration.

The most interesting article which I have seen is that of Lt. Col. Camac of New York, and his associates, coming from observation at General Hospital No. 6, Fort McPherson, Georgia, which was published in the December number of the *American Journal of the Medical Sciences*. They treated 81 cases of uncomp'icated pneumonia, 26 type I, 18 type II, 10 type III, and 27 type IV, with only two deaths. The two fatal cases were complicated with nephritis, one chronic the other acute; both colored men, and stevedores. Mulford's polyvalent stock serum was used in most cases, but in some the type I serum was used when typing was done promptly. As this polyvalent serum is made in such manner that the type I element is not neutralized, it is quite unnecessary to have the typing done. This leaves the way clear for the immediate administration of polyvalent antipneumococcus serum, after the patient has been desensitized by the subcutaneous injection of 2 c.c. of serum. The article goes into full detail regarding the use of the polyvalent serum and the results obtained, and I would urge every physician to become familiar with it. Camac makes the rather significant, if not surprising, statement that "uncomplicated pneumococcus infection is a comparatively harmless and rarely a fatal condition."

In the *Journal of Medical Research* of July, 1918, Kyes reports 115 cases of acute lobar pneumonia in which the patients were treated with an antipneumococcus serum, and compares the mortality among these cases with the mortality in 538 similar cases of pneumonia occurring in the same institution during the same period, but not so treated. The antipneumococcus serum was produced by injecting massive doses of virulent pneumococci into the domestic fowl. Of the 538 patients not treated with the antipneumococcus serum, 244 died—the death rate being 45.3 per cent. Of the 115 similar patients treated with serum, 24 patients died, the death rate being 20.8 per cent. In the ward in which the serum was employed the death rate during the weeks prior to the introduction of the serum treatment was 55 per cent. These statistics show that among those cases treated with the antipneumococcus serum the death rate was less than one-half the rate obtaining among the similar cases not so treated, whether they were cases occurring in other wards during the same period, or in the same ward at other periods of the same year. This is essential proof which Kyes has to offer that the antipneumococcus serum in question is of distinct value in the treatment of acute lobar pneumonia in man.

In the treatment of post-influenzal pneumonia quite a little has been done with convalescent serum; that is, the intravenous injection of the serum from the blood of patients convalescing from influenza pneumonia. Lieutenant Kahn of New York treated 25 patients with convalescent serum at Camp Zachary Taylor, Louisville, Ky. These patients were all in bad shape with extreme toxemia, dyspnea cyanosis, and extensive lung involvement, the mortality being 48 per cent. as against 66.6 per cent. in control cases. O'Malley and Hartman of Washington treated 46 cases with a mortality of 6.5 per cent. while of 111 cases untreated 25.2 per cent. died McGuire and Redden of Chelsea, Mass., Base Hospital, treated 37 cases with one death, and so on Theoretically, at least, this seems to be the idea treatment for pneumonia complicating influenza. I promises much in the future. Maclachlan and Fetter of Pittsburgh have used citrated blood instead of serum, which method has some advantages, but the results do not seem to be so good.

Quinine has its many advocates in the treatmen of pneumonia, and it certainly would seem to have more than ordinary virtue as a pneumococcus destroyer. It has been my practice during this season to give fairly large doses of quinine sulphate by the mouth in the few cases of lobar pneumonia and the many cases of influenzal pneumonia that have treated, but I am not prepared to say with what results. Waters and Elliott Burrows of New

York have treated several cases of influenzal pneumonia by the intravenous injection of quinine dihydrochloride, with very satisfactory results. As a prophylactic against pneumonia and also influenza I think its value cannot be questioned.

Vaccines have been used for some time in the treatment of pneumonia, but there seems to be some opposition, or at least skepticism, on the part of teachers of authority regarding their value except, perhaps, the autogenous vaccines which are given more credence. My personal experience with mixed vaccines in the treatment of influenza pneumonia has been rather gratifying, but I am not at present prepared to make any statement that would appeal to the scientific mind. At Fort Oglethorpe, Smith, Dare, and Bergey have treated over 100 cases of pneumonia with mixed vaccines with a mortality of less than six per cent. Not only was the mortality lessened but the duration of the disease was shortened, the patient's comfort promoted, and the incidence of suppurative complications decreased almost to a negligible point.

Complaint may be made that all these methods are beyond the reach of the general practitioner, but such is not the case. Any doctor or nurse not familiar with the procedure can learn to count blood cells in a very short time, and the necessary implements are inexpensive. The technique of intravenous medication is nearly as simple as the hypodermic method and we should all be familiar with it.

The preparation and administration of convalescent serum and citrated blood is another matter, however, and requires adequate laboratory facilities and the cooperation of an experienced pathologist.

With these measures reasonably available in country and city, I think that we should all feel encouraged in our attempts to fight pneumonia. At the present time these methods are the best that we know anything about and our patients are certainly entitled to the benefit of any doubt in the matter. The administration of serums and vaccines is along scientific lines and will certainly lead the way to the best results.

I shall hope that these remarks may serve to turn my readers from the old routine in the treatment of pneumonia. In my opinion the most serious error is procrastination—in this connection the thief of life as well as the thief of time. The administration of expectorants and cough mixtures is fast going out of style and codeine, heroin, or morphine is depended upon to give the patient needed rest. Strychnine is no longer a favorite as a heart tonic or stimulant and most of have learned that nitroglycerin is a vasodilator and not much more. In pneumonia it would be contraindicated.

Adrenalin, camphor, ammonia, and alcohol are indispendables and should be used on occasion.

Summary.—1. Attack pneumonia with the idea that it can be successfully treated.

2. Make early diagnoses, giving the patient the benefit of any doubt by instituting early treatment.

3. Digitalize the patient by the Eggleston method at once.

4. When the leucocyte count is high and lobar pneumonia is determined, give polyvalent serum according to the teaching of Camac and others. Do not wait for typing.

5. When the leucocyte count is below 7500 and the clinical evidence supports a diagnosis of post-influenzal pneumonia, give convalescent serum if possible. Give the mixed vaccines and quinine due consideration.

6. Fight the disease to the last ditch.

RADIOTHERAPY IN CANCER: SUMMARY OF SIX YEARS EXPERIENCE IN THE TREATMENT OF MALIGNANT DISEASES.

By MAURICE J. SITTENFIELD, M.D.,

NEW YORK.

It would be profitable perhaps after six years experience in Radiotherapy to take stock, so to speak, sum up our results, check up our errors, and correlate our experiences with those of other coworkers and writers. An analysis of these will make for a better understanding of our shortcomings, and may lead to a possible stimulation to get together and standardize our technique. Among the many thousands of cases reported in the last six or seven years, many brilliant results have been obtained. Unfortunately, however, no standard regarding technique or scale of dosage has so far been established and every worker is using his own technique in as far as the administration of the dosage—the filtration, the focal distance, the penetration, and other important factors is concerned. Hence the quality and quantity of irradiation administered by the different therapists is not a uniform one. Aside from this, not sufficient importance has been accorded the selectivity of the cancer cases, the local and general dissemination, the length of duration of the tumor, and its biological behavior. There is a remarkable difference in the opinions and reports concerning the amount of dosage used by different workers, and a lamentable absence of description of the dosage, especially by our American coworkers. I appreciate the fact that everyone has to work out his own technique with his own apparatus and the dosage required in a given case, but after numerous experiments and a number of years experience, a certain standard, within a certain range, can be set up, and no one so far has attempted to put into effect such a scale of measurement. A great many writers describe brilliant results with very large and intensively massive doses, others obtain equally fortunate results with very small doses, but so far the exact quantity and quality of the radiation has been mentioned, with few exceptions, only by foreign writers. In the radiotherapy of cancer my own experience teaches me that only massive doses with our present apparatus can be considered. Here I do not wish to enter into a discussion of the advantages of the γ-rays of radium and the hard and penetrating rays emitted by the Coolidge tube. Kelly, Burnham, and others claim the superiority of γ-rays

qualitatively, while Döderlein, Bumm, Warnekros, Dessauer, and a host of others have proved experimentally by the present means of measurement that *x*-rays have 5,000 times and more the quantity of radium and mesothorium rays. For instance, it required 11 hours for 200 mg. of mesothorium to equal the dosage of 10 minutes radiation from the *x*-ray tube. Case, Pfahler, and a number of others are agreed that qualitatively radium has no advantage, and perhaps the very best results are obtainable by using the combined method of radium and *x*-ray.

It is pretty well accepted, however, that in small, superficial, local lesions radioactive substances can be used to good advantage, while in deeper located cancer and that involving larger areas, the Roentgen ray through a high vacuum tube, as the Coolidge, is to be preferred. It would be of immense value and interest aside from other considerations, if a recognized standard of measurement of the absorption of radiation by a given tissue could be determined. The value of the different instruments over one another is negligible and so far no uniform index as to measurement and dosage is available.

At present we use an arbitrary unit of radiation, i. e., the quantity necessary to cause an erythema of the skin. This unit is determined by some by the Holzknecht Quantimeter, others use the Kienbock photochemical strips, still others the Sabouraud-Noiré pastilles, and so on. Attempts to simplify the measurement of the dosage have been made by means of the electroscope, but this seems so complex a method that only physicists are able to manipulate it. Other efforts have introduced the Iontoquantimeter, which depends upon the ionization of the air. This also is rather complicated, and therefore not a popular instrument. Next we have the Furstenau Intensimeter; this records the dose through the deflection of a selenium needle. Perhaps up to the present this is the least objectionable and most acceptable of any. Besides there is the Christen instrument, and a host of others depending upon photochemical and biophysical measurements. Duane of Boston has devised an ingenious instrument which is not perfected enough to make it accessible for the ordinary radiotherapist. Therefore it is of greatest importance that some indicator be constructed and adapted which will measure the dose during the radiation, instead of determining the dose after the radiation by photochemical or any other of the above methods.

Filtration.—In the matter of filtration we are again at sea, though not quite as helpless. Almost everyone uses at least 3 mm. of aluminum. Some claim that 3 mm. are not sufficient and use from 4 mm. up to 7 mm. Another set of workers uses 0.5 mm. of zinc, others use brass, and so on. It can be stated from personal experience that 3 mm. sometimes, but better 4 mm., of aluminum plus 2 mm. of leather gives ample filtration. Here, however, I wish to differ with some writers who claim by use of the filter never to have seen burns even of the first degree. In my own work and that of others who are equally careful, once in a great while a burn of the first and even of the second degree does occur. In fact in reviewing the literature I have come across the very best *x*-ray workers admitting that in some cases burns are absolutely unavoidable, in spite of the most careful filtration. Yet I would urge the greatest care, and I trust that with more and more experience this unfortunate occurrence will be entirely eliminated.

Focal Distance.—Not enough attention is given to this phase; rarely is it mentioned by our coworkers here, though the foreign writers give it more than a passing thought. A great many experimental efforts have been described. Case, among others, has shown that a focal distance of 7 inches produced an erythema dose in 18 milliampere minutes, and that with a focal distance of 10 inches it required 37 milliampere minutes; with 14 inches, 72 milliampere minutes. It is obvious therefore that the ideal method is the one that effects the largest dose in the shortest time. My own technique is to administer the treatment within a focal distance of about 6 inches wherever it is possible.

Penetration.—Here perhaps lies the most important factor in Radiotherapy. Every apparatus and every tube should be devised so as to furnish the maximum of radiation and to do this in the most constant, reliable and dependable manner. Fortunately the improvement in our tubes in the past four or five years has made possible a vast progress in Radiotherapy, and by means of the Coolidge tube a constant high penetration can be demanded for an unlimited time. Unquestionably this tube will be so improved that a still higher penetration can be obtained. After all this is the factor which will give us better results. If we can reach a point say 5, 7 or 8 inches beneath the surface of the skin by means of our irradation in sufficient quantities to influence the tissues, then we can equal the effects we now obtain in the more superficially situated cancers. Our handicap at present lies in the limited amount of radiation that is left to be absorbed by the deeper tissues. It is well known to everyone that only about 1/7th of the surface-dose affects the tissues 10 cm. in depth.

The previous remarks indicate the difficulties we are laboring under at present to arrive at a clear-cut method of administering radioactive substances. Yet everyone must be impressed with the progress in this field of therapy notwithstanding our lack of uniform technique. In this series of 94 carcinomata which I wish to report here, there were 15 of the face, mouth and throat; among these were 7 cases of basal cell epitheliomata of nose, ear, lip, cheek, et cetera, everyone of which yielded to the treatment, and has been free from recurrence one to six years. The three squamous cell epitheliomata of the antrum complicated with ethmoidal and sphenoidal sinus involvement, the two of the tongue and the three of the tonsil involving the pharynx and larynx were not as satisfactorily influenced. Out of these eight, hopelessly inoperable, two are still alive, one has been clinically cured for the past four years, and the other is very much improved, but of too recent date to report definitely. One man, 82 years of age, with a spindle cell sarcoma of tonsil, pharynx and larynx, lived for two and a

half years and died of metastases in distant organs. Eight cases of carcinoma of the breast with no glandular involvement which was radically removed, were treated prophylactically immediately after discharge by the surgeon, and are clinically cured for a period ranging from one to six years. Of fourteen treated for later recurrences in the scar, axillary or superclavicular glands, all but three (one is still alive after four and a half years) succumbed. Two of these cases showed pulmonary involvement and were relieved for a short time. The effect of the ray was at best only palliative in sixteen inoperable cases of carcinoma of the viscera—stomach, liver, pancreas, kidney, and so on. During the treatment their distress, dyspnea, and pain were considerably relieved, and a marked improvement seemed evident psychically. Almost everyone remarked that he experienced relief from his pain, became more cheerful, and exhibited a feeling of hopefulness which was shared by his family. Ten cases of uterine cancer were treated after discharge from the hospital, and five, or one-half, are free from recurrences over a period of one to five years. Eleven other patients with recurrent uterine carcinomata were rayed—of these three are still alive. One case is of too recent date to report, though her condition is so much improved that we may look forward to a good result. Out of six cases of inoperable carcinoma of the prostate one is alive after three years. All were in rather bad shape and the treatment brought great relief. Five, however, finally succumbed to metastatic involvement elsewhere. The response in four carcinomata of the bladder was not entirely satisfactory; for a short time there was a slight improvement in two, one is still alive, and the other lived for two and a half years in comparative comfort until metastases in the abdominal viscera and ascites developed. Two cases of sarcoma of the testes, one of them postoperative, reacted well; one man is alive after four years, and the other when last heard from was clinically cured. One patient of three with postoperative recurrent sarcoma of the bone is clinically free from malignancy. Of five cases of lymphosarcoma, three are clinically cured, one among the earliest cases has remained free from recurrence for nearly six years, one is a patient with cylindroma of the submaxillary gland which had been removed surgically, and the other is a case of two years duration and is still under observation. Aside from this series of ninety-four, five cases of Hodgkin's disease were given the benefit of radiation but did not yield satisfactory results. One woman lived five years, another three years. The latter patient died of a *streptococcus hemolyticus* pneumonic infection.

Analyzing our results we can not point to our success with any special pride. Some of our failures, however, were due perhaps to early inexperience with our apparatus and inadequate tubes. With the advent of the Coolidge tube and greater experience in Radiotherapy our percentage of successes has been increased. I am learning, as I go along, to administer larger doses and not to be so apprehensive about skin lesions. Seventy to one hundred Kienbock units are frequently applied over a skin area in one series, and during the month one hundred and fifty to two hundred Kienbock units are tolerated fairly well. With an increased knowledge of technique better results are to be looked for. Since the fact has been established that cancer cells can be rendered harmless and their clinical malignancy destroyed by irradiation. Their reproductive mechanism is interfered with as our histological studies prove that radiated tissue has lost its malignant nature. Our efforts therefore should be directed to the finding of possible ways and means of affecting all the cancer cells in the body. After all, the final test of the cure of cancer is not alone whether we can destroy cancer cells but whether we can rid the body of them.

There are, however, other factors which have a definite bearing on many of our failures, namely, the biological behavior of the tumor, whether it is richly cellular, vascular, young and rapidly growing, or fibrous. Studies by Ewing point out that cellular and rapidly growing tumors are most favorably acted upon, and that those which are made up of old fibrous tissue as, for instance, tumors of old Hodgkin's disease or granuloma malignum are not very responsive. Tumors of long standing and wide dissemination are most difficult to influence. Biologically no two tumors behave alike clinically, though to all intents and purposes they may be of the same age, size, and affecting the same locality in the same organ. The ability of the tissues around the tumor to produce a cellular, inflammatory exudate of leucocytes, lymphocytes, plasma, and wandering cells aside from the constitutional resistance of the host and his ability to throw off and absorb the radio-acted upon substances, must be taken into account.

For the constitutional resistance of the patient unfortunately we have no dependable index, as none of our experimental hypotheses are clinically borne out. We know at present of no specific agent which has anything to do with immunity, natural or acquired, in cancer. Ehrlich's theory of athrepsia is pretty well exploded, and there is no definite relationship established between panimmunity and cancer. The hypothesis of Murphy that the number of small mononuclear lymphocytes in the blood is the factor which determines the behavior of experimental cancer, i. e., a high percentage of lymphocytes is indicative of a high state of resistance, does not hold true in the study of clinical cancer. Personal observations on the lymphocyte count in cancer patients corroborate my experimental work in white rats. In nearly all of my cases the lymphocyte count ranged from 25 to 45 per cent., and even in the most severe cachexias, a lymphoid count of 33 per cent. was encountered a week before death. These findings are in accord with the studies of Millet and Mueller, who also claim that the percentage of lymphocytes in the blood is not a guide to the state of resistance of the patient.

Another very important factor which bears upon the ultimate results of our radiotherapy is the stage at which the treatment is administered, whether the prophylactic, the recurrent, or the cachectic stage. By the prophylactic stage I re-

fer to that period at which the surgeon co-operates with the radiotherapist as soon as the patient recovers from the primary operation. Radiotherapy then offers the most hopeful results. Of course even at this early period we encounter at times failures, but these are due not to the non-effect of the radioactive substance, perhaps, but to the conditions mentioned above. My own results correspond with those of Loose, who reported 55 cases of carcinoma of the breast with no glandular involvement which were rayed immediately after the operation with not a single recurrence over a period of three and a half years. When the lymphatic glands were involved, however, the results were not as satisfactory. Bumm and Warnekros report a series of 174 cases of carcinoma of the uterus operated upon in their clinic during 1911 to 1914. Of these 119 were not treated with radiotherapy after the operation, and 66 died of recurrence. Fifty-five women were systematically rayed after the operation; of these 11 died of recurrences, i. e., those without radiation after the radical operation showed a mortality of 55 per cent. against 18 per cent. of those receiving the benefit of radiation. Seitz and Wintz, a few months ago, wrote of a series of 52 carcinoma of the uterus since 1915. Twenty-eight of these were favorable for operation and 43 per cent. are alive after 3 years. The other 24 cases were inoperable and therefore subjected to radium and *x*-ray only; 46 per cent. are clinically cured. Eleven out of the latter series were considered absolutely hopeless and 1, or 9 per cent., is still alive.

A study of these results must make it appear that radiotherapy is an important step forward in our attack against the inoperable cases of carcinoma of the uterus, breast, and so on. If we compare the end results of such cases treated by any other method with those treated by radiotherapy, we must conclude that irradiation is an advance in our battle against cancer. Even in the most hopeless cases, it at times surprises the radiotherapist, inasmuch as a most desperate case may become not only operable but clinically cured. In almost all inoperable malignant conditions the patient after radiation enjoys a sense of improvement, his intense pain is diminished, it becomes more tolerable, he is able to sleep, begins to feel hopeful, and his burden and that of his family is lessened.

I fully agree with T. C. Kennedy, who says: "The great value of radiation can be judged only by keeping constantly in mind the fact that only the hopelessly incurable or patients with marked postoperative recurrences are sent for radiotherapy. If we relieve a small percentage and occasionally cure a patient who has been operated upon or refused operation on account of the seriousness of his condition, we have done much for suffering humanity."

In conclusion, among the points which stand out most prominently in my experience is the lack of early cooperation of the surgeon with the radiotherapist. The carcinomata of the breast and uterus which were rayed immediately after discharge from the primary operation showed a most astonishing percentage of clinical recoveries, in my own cases as well as those reported by Loose, Bumm and Warnekros, and a number of others.

In striking contrast to the results formerly obtained in the inoperable cases, we can point now to our results, which are not quite as satisfactory as those of Seitz and Wintz, who claim nearly 50 per cent cures. Duane and Greenough report a series of 1,089 cases treated at the Huntington Memorial Hospital, 55 per cent. of which were definitely benefited. A certain proportion can be made operable, or may be clinically cured. Some clinical cures date back six years, the length of time that these cases have been treated with intensive radiotherapy. With every subsequent recurrence, however, the resistance to radiotherapy grows greater.

Unfortunately a great deal is expected in the cachetic cancer patients, and perhaps this is the cause of the apprehensions with which many view the apparent failure of radioactive substances. Yet every once in a while the most hopeless and desperate case may repay us for our painstaking effort, aside from the psychological benefit which is derived by many. Careful blood examinations must be made during the treatment, in order to avoid injuring the blood elements beyond reparation.

In the selectivity of the cases for radiotherapy, in addition to those just mentioned, the superficial basal membrane epitheliomata are best adapted, for in them in almost every case a favorable outcome can be expected. The squamous cell epitheliomata are not as amenable. Localized round cell sarcomata react more readily than do carcinomata.

The biological behavior of the tumor must not be lost sight of. This constitutes perhaps the most important factor in the response to our treatment, namely, whether the tumor is made up of richly cellular tissue or of old fibrous tissue, the latter being the most hopeless of any.

Furthermore it would be of greatest advantage when making casuistic reports to dwell upon the exact measurement of dosage, penetration, focal distance, filtration, et cetera, in order to arrive at some elastic standard of dosage.

73 East Ninetieth Street.

MYRISTICA (NUTMEG) IN THE TREATMENT OF AMEBIC DYSENTERY.

By Joseph Leidy,
Philadelphia.
Captain M. C., United States Army.

Avicenna[1] recommended myristica for the cure of chronic fluxes dependent upon ulceration of the bowels. Hildanus[2] adopted these views, and assigned nutmeg a high place among the simples (herbs) by which the bowels may be restrained in dysentery. Penrose,[3] during the War of the Rebellion, stated the remedy which had been most positive in their results, after opium, had been nutmeg with oxide of zinc. Woodward,[4] in his classical treatise on "Dysentery and Its Treatment," refers at length to nutmeg, and is in accord with the views of other writers that it eases pain, but is not disposed to credit it with having advantages over other remedies.

Oxide of zinc, with which it was combined by Penrose, was later abandoned on account of the increased nausea and diarrhea which were produced; carried to the bowels without any action in the stomach, it was considered sedative. Nutmeg, on the other hand, unites with the medicinal properties of the ordinary aromatics considerable narcotic power.

During the past year the writer has had an opportunity to follow the course of a case of amebic dysentery, contracted by an officer in one of our Southern camps, which has resisted treatment with emetine. To emetine he evinced a marked idiosyncrasy, which was attended with great prostration and increased diarrhea.

Until recent years the treatment of dysentery was largely empirical, which doubtless explains the successes and failures obtained by our army surgeons during the Civil War with ipecac. It doubtless explains why emetine fell into disrepute both by mouth and rectal injection. Prof. A. E. Shipley of the British Educational Commission, on a recent visit to this country informed the writer that even in amebic dysentery it had not come up to expectation in the Salonica campaign. It is of interest to note that Woodward states emetine is contraindicated in asthenic cases or when diarrhea is increased. It was under this type the patient was classified. The stools contained both the free motile and cystic forms of *Endamœba histolytica;* the patient was resistent to treatment, there being frequent exacerbations, with prostration and loss of weight; during the intervals of the acute attacks the patient would improve, but the stools showed the persistence of the cystic forms, with extensive trichomonas infection. There were, in addition, the accompanying symptoms of colitis.

In view of the success obtained by Penrose in the group of cases which he reported it occurred to the writer that possibly the essential oil of myristica may have acted as an amebacide, which would account for the success which he claimed for the treatment. The patient was placed upon 30 grains of selected grated nutmeg three times a day, care being taken to obtain a pure product. The effect of treatment upon the subjective symptoms was decided and prompt; the frequent spasmodic (colitic) pain disappeared; three days later, examination of stools showed fewer cysts, with abatement of the *Trichomonas intestinalis* infection. At the expiration of seven days very few cysts were found; the patient has shown steady improvement in his physical condition. Three weeks after treatment no cysts were found. Regular examination of the stools for the past four months, by the ether centrifuge method, has been negative, as to both the vegetative and the cystic forms.

The question naturally arises, have we in the essential oil of nutmeg an amebacide? Or are the gastrointestinal secretions so influenced as to preclude the harboring of the parasite? The action of many essential oils is well known. The use of highly seasoned condiments in the tropics is well known. Have we in these preparations substances which protect individuals from parasitic infection? The subject is well worthy of further investigation.

Medicinal Properties.—Nutmeg has long been used as a carminative, anodyne, and astringent. It is a narcotic, and has been used as a soporific. In England and India it has been resorted to as an emmenagogue and abortifacient. According to Cushny,[5] until this year (1908) no textbook referred to oil of nutmeg poisoning. Medical literature, however, contains a number of references, Lobelius[6] (1756) and Paullinus[7] (1704) refer to its poisonous action.

In recent years, Wallace[8] (1903) collected 25 cases with one death; the quantity ingested approximated from 1 to 1½ grated nutmegs. One case of poisoning is reported after the ingestion of 1 drachm of mace. The symptoms developed in from 1 to 6 hours. There is drowsiness passing into stupor, from which the patient can be roused with difficulty; he is unable to recognize his surroundings. Diplopia has been observed, with evidence of mental depression; at times there is marked excitement and delirium before the stupor suggestive of cannabis indica poisoning. Sometimes the first symptom is abdominal pain attended with precordial distress and giddiness; in two cases alarming collapse occurred. The stupor lasts from 4 to 6 hours, passes off, and the patient recovers. The only death recorded is in a boy of eight, who swallowed two nutmegs and became comatose, from which condition he could not be aroused, and died in 20 hours.

Nutmeg contains 3 to 8 per cent. volatile oil; when this is extracted the residue produces no effect whatever in animals. The oil contains several terpenes, pentene, and dipentene. The pentenes are devoid of action except in large quantities. The constituents of the fractional distillation have been isolated as myristicol and myristicin.

According to Wallace, experiments upon rabbits and frogs were followed by depression, paralysis, and loss of reflexes. The cause of death is failure of respiration; the heart continues to beat for some time afterward. The cat is more susceptible; there may be vomiting and purging, the wall of the stomach is red and injected, the urine contains albumin. When large amounts of the oil have been given the urine contains a substance, not sugar, which reduces Fehling's solution, turns the plane of polarized light to the left; this is probably glycuronic acid (Wallace).

Dale[9] observed fatty degeneration of the liver, which developed several days after apparent recovery in animals, being preceded by jaundice.

Two nutmegs weighing approximately 10 grm., containing 1 gm. of the essential oil, caused poisoning in animals.

Dosage.—A dose of 25-30 grains of powdered nutmeg was administered three times a day after meals for one week, the second week twice daily, the third week once daily combined with a simple digestive powder. The oil of nutmeg was not used owing to its irritant properties. The dose as recommended in the U. S. Dispensatory is 2 to 5 drops, 0.10 to 0.25 c.c. The pure grated nutmeg is preferred.

Conclusions.—With the demobilization of our army, from what the writer observed in a number of our army camps, he is of the opinion that amebic dysentery will become more common in the United States than formerly.

In view of observations made by others, and those

of the writer in the treatment of dysentery of the parasitic variety, due to the *Endamœba histolytica*, the use of nutmeg should be given a fair trial, particularly in the case of carriers.

Diagnostic Precautions.—Care should be exercised in collecting stools for examination. We found that active motile forms of endameba frequently became immobile within one-half hour after passage unless preserved in an incubator. For doubtful cases, bedside examinations should be made, and in addition the ether centrifuge method, adopted by the U. S. Army, should be resorted to for detection of cysts and checking of carriers.

Technique.—The following method of examination in use at U. S. Army Medical Laboratory School, New Haven, Conn., for ameba cysts is recommended to replace direct smear examinations and the centrifuge method for the detection of protozoan cysts. It is a modification of the methods of Cropper and Row (*Lancet*, v. 192, p. 179) and of Carter and Matthew (*Am. Jr. Trop. Med. and Paras.* v. 11, p. 195) used in the State Board of Health (see Boeckm Univ. of Cal. Pub. Zool., v. 18, p. 145). Its value lies in the concentration of cysts from a large sample and the differential staining of the centrifuged cysts and sediment. Concentration is secured as follows: One grain of stool is mixed in an electric soda mixer, in a tumbler with 30 c.c. of normal saline solution, for ten minutes, until a complete suspension is obtained. While still stirring, add 5 c.c. of ether. The ether settles the foam at first, but the suspension soon begins again, usually in two or three minutes. Stirring should cease the moment the foam begins to rise. The fluid is poured at once into a separatory funnel and allowed to stand from five to seven minutes, during which cysts and heavier débris sink. Draw off 15 c.c. and centrifuge for three minutes at 1600 revolutions per minute; examine the sediment for cysts.

Differential staining is secured by adding 5 c.c. of N10.000 solution of neutral red at the end of eight minutes, stirring with the soda mixer. Lightly stained or unstained cysts stand out amidst the more deeply stained débris, and are easily distinguished from the more deeply stained intestinal yeasts. Nuclei, axostyle, and intracycloplasmic flagella of cysts of Giardia are lightly stained. Instead of using neutral red in the mixer, a drop of the solution may be added to the sediment on the slide. Gram's iodine solution may be added to the sediment to differentiate the nuclei of endameba (see Stitt, Pract. Bact., p. 265). By direction of the Surgeon General, War Department, August, 1918.

Note.—In the preparation of Gram's iodine solution the writer has found that any soluble iodide of metal (sodium, magnesium, aluminum, arsenic ferrous, ferric iodide) may be substituted for iodide of potassium in the preparation of Gram's iodine solution in similar proportion; this will give equally satisfactory results as a substitute for staining positive bacteria as well. In war time the cheapness of the iodides of arsenic and iron makes them desirable substitutes.

The writer wishes to express his appreciation to Col. C. F. Craig, M. C., commanding officer in charge of Yale Army Laboratory School, for his assistance in checking the pathogenic form of the endameba in this case.

USE OF MUSK IN PNEUMONIA; NOT A SCIENTIFIC DRUG, AND SUBJECT TO GROSS SUBSTITUTION.

By WALTER C. ALLEN, M.D.,

CHICAGO.

DURING the epidemic of so-called influenza which we have just passed through, musk seems to have enjoyed a recrudescence, merited or unmerited, in the therapeusis of the associated pneumonias; at least that is the inference drawn from the statements of two of the best known internists of Chicago. Each of these men, whose writings have appeared in recognized American medical journals for years, has stressed the use of a drug almost forgotten. One of these internists described his use of the drug before the North Shore Branch of the Chicago Medical Society. The other mentioned it during his regular Saturday afternoon clinic.

Musk is the dried secretion of the preputial follicles of the male *Moschus moschiferus*, or musk deer.[5] The habitat of this deer is, for the most part, in China, Thibet, and the Himalaya Mountains. The best-known varieties of musk come from China and Siberia, and the better of these is that from China, known as Tonquin musk.

Tonquin musk is very expensive. Before the great war of 1914-1919 only 300 caddies of it were imported yearly from Shanghai to New York. Thirty ounces of musk granules are obtained from the contents of a caddie. These caddies are containers similar to but very much smaller than tea chests. It is impossible to obtain from a pharmacist musk for less than twenty-five cents a grain, and of course, musk offered for less than that may be looked upon with suspicion. As a matter of fact, the chances are that prices quoted would be very much higher on account of the present difficulties of importation. If a dose of fifteen grains were to be given, it would easily cost about $4; and then if the dose were to be repeated three times daily, one can easily see that only "malefactors of great wealth" could command its use.

In using musk, one must be sure that the pharmacist has furnished real musk. The physician will have to depend upon a high-class pharmaceutical house. No reflection upon dispensing druggists or pharmacists is to be inferred from this

statement, but there has been so much hokus-pokus and chicanery associated with the production of musk that even the pharmacists are imposed upon, and think, in good faith, that they are dispensing a reliable drug, when in reality some worthless substitute has been foisted on them.

The root of the evil seems to center about the fact that there is only a limited supply of musk, that this supply is decreasing, and that musk has a characteristic odor which has created a demand for it in the preparation of perfumes.

The fancy prices which the Chinese, Siberians, and Indians of the Himalaya districts have been able to command for musk have tempted them to trick dealers. After extracting all or most of the musk granules from the sacs of the male musk deer they have habitually made gross substitutions with such material as dried blood, resin, hair, bird dung, wax, storax, benzoin, and asphaltum, materials absolutely inert. They then carefully sew up the sacs and sell them as though they were the original musk sacs.

The U. S. Formulary, and other texts of a similar nature, however, give adequate detailed descriptions of tests which, if the pharmaceutical houses will but use, protect them against such substitution. An acceptable test is that described by Bernatzik and given in the German pharmacopeia, viz., the examination of the material spread out in a thin layer under turpentine, and examined by microscope, when the musk appears as diaphanous brown amorphous splinters.

Fresh musk has an intense, offensive, penetrating, peculiar, and persistent odor. Much of this odor is lost on drying, but so much remains that it has been used for ages in making perfumes. The demand for musk for perfumes has been met by A. Baum,[5] who was successful in isolating the active constituent upon which the odor depends, a ketone, which he named muskone. He then built up the corresponding synthetic chemical, tritertiary-butyltoluene, $C_6HCH_3(NO_2)_3C(CH)_2$, commonly known as artificial musk.[13] As this compares favorably with natural musk, it has supplanted natural musk in the perfume industry. It should be remembered, however, that this artificial musk has none of the medicinal properties of natural musk, unless one is to consider the possible psychic effect of the odor of the product as such.

The fluidextract of musk root, sumbul radix, has been palmed off as musk, and is said to have been used as a substitute for musk by the Russians as early as 1835. In spite of extravagant claims, it has nothing in common with musk, except odor.

The dried secretion of a sac of the American muskrat has also been used as a substitute, but this, too, has nothing in common except odor.

Some droll stories cluster about musk. The memoirs of Nicholas of Russia record that the last dose he swallowed before death (1855) was a potion of musk. The tale goes that Empress Josephine, much to the annoyance of Napoleon, who hated the stuff, used musk profusely about her boudoir, and that the odor persisted for forty years after! Musk is still held in high repute among Eastern nations. Even Shakespeare, in "Merry Wives of Windsor" dropped a line, "So sweetly, all musk," about this penetrating drug.

Hager[7] names the constituents of musk as follows: fats, cholesterin, wax, biliary matter, mucus, albumin, traces of lactic, butyric, phosphatic, and sulphuric acids, traces of ammonia, and a volatile oil.

An analysis of musk by Geiger and Reiman, quoted by Gmellin,[6] shows that it contains cholesterol, 0.5-2.07 per cent. of a volatile oil, fatty, waxy, and albuminous substances, and the ketone, muskone.

A convenient vehicle for musk is the tincture[11] prepared as follows:

Musk	5 gm.
Alcohol	45 c.c.
Water	45 c.c.
Dilute alcohol q. s. ad	100 c.c.

Triturate the musk with water a little at a time until a smooth mixture is obtained. Transfer the mixture to a bottle and let it stand twenty-four hours. Add alcohol. Macerate mixture for six days, occasionally shaking. Filter. Pass dilute alcohol through filter to make up to 100 c.c. of solution. Dose, dram 1 or 4 c.c.

The literature[1,2,3,12,15,16,17,19,20] gives the following actions of musk, without, however, experimental data as control of observations: deodorant, antispasmodic, diffusible stimulant, sedative, aphrodisiac.

Diseases or conditions in which musk is said to have been effective are as follows: bronchiectasis, convulsions, hiccough, hysteria, epilepsy, flatulence, pneumonia, singultus, subsultus tendinum, laryngismus stridulus.

Musk has had an illustrious past, and at one time a tremendous vogue. The great and conservative French physician, Trousseau, commended it in the treatment of pneumonia, especially that of drunkards with cerebral symptoms.

Musk as a stimulant is discussed by Allbutt and Rolleston[1] as follows: "In former days musk enjoyed a high reputation as a diffusible stimulant and antispasmodic in the low muttering delirium and nervous prostration of the ataxic state. In Ireland, however, of late years, this remedy has fallen into unmerited disuse, partly because of the great cost of the drug, and partly, it is to be feared, because its exhibition was postponed until too late to prove of much value. In an epidemic of typhus, in 1866, Dr. Clifford Allbutt found musk most valuable when given in five-grain doses in low delirium. It may be prescribed in bolus or emulsion. Camphor may be substituted for musk in hospital practice, or these powerful diffusible stimulants may be given in combination."

No less brilliant an internist than the late Dr. Henry L. Elsner of Syracuse, writer of the section on the treatment of lobar pneumonia in Forchheimer's Therapeusis of Internal Diseases,[4] discussing hiccough, notes: "In many cases there is prompt recurrence of hiccough, with great prostration. Under these desperate circumstances, when patient and physician were discouraged, musk 0.06 gram (1 gr.) in capsule, every two to three hours, and an occasional morphine injection, have helped. With sustained improvement the hypodermics may be discontinued, but the musk should be continued for several days."

Musser and Kelly[10] add to the sum total of our

knowledge of musk as follows: "In bronchiectasis, when the sputum comes up in very large quantities and has a most disagreeable odor, musk covers the smell and helps the patient. Musk is, indeed, a useful respiratory stimulant, and in cases of pneumonia, when the respiration appears to be failing, the tincture of musk—although the remedy is now looked upon as almost obsolete—is, I believe, really very useful, in doses of 1 dram every two hours." Striking testimony that this drug is, indeed, considered almost obsolete was given in 1914, when it was deleted from the British pharmacopeia.

Hatcher and Wilbur[8] note that a century ago musk was considered a powerful circulatory stimulant, and that in our times Solomon Solis Cohen has recommended it as an efficient and dependable remedy when it can be obtained in pure form and of good quality; but that, as noted elsewhere, it is extremely expensive and subject to gross adulteration.

Continuing, Hatcher and Wilbur state: "Musk probably resembles camphor in action on the centers, and has the advantage of greater solubility in proportion to the amount required. Castor fiber and sumbul root, which have been recommended as substitutes, are entirely devoid of any such action as that claimed for musk. Musk may be given in capsules or tincture."

Finally, it remains to emphasize the fact that the use of musk is purely empirical, that its active principle has never been isolated, and that, in consequence, statements as to the action of the drug have not been backed up by experimental data.

Dr. Hans H. Meyer of Vienna and Dr. R. Gottlieb of Heidelberg,[9] who had occasion to review the literature on musk, say: "Musk was formerly much used for the same indications as camphor, but to-day it is used but seldom, and is no longer official. There are no experimental investigations which would justify its use clinically."

PECULIARITIES IN THE SYMPTOMATOLOGY OF EXOPHTHALMIC GOITER.

By ISRAEL BRAM, M.D.,
PHILADELPHIA.
INSTRUCTOR IN CLINICAL MEDICINE, JEFFERSON MEDICAL COLLEGE.

The increased attention given by the medical profession to the subject of endocrinology, especially to the study of the thyroid gland, is not without cause. And though on the one hand we have not made much advance in concrete or specific information concerning the etiology and pathology of diseases of the thyroid gland, especially of Graves' disease, we may on the other hand look back with pride upon the last decade and its vast quantity of suggestive material which is in store for the investigator.

Various factors are responsible for the undoubted increase in the number of cases of Graves' disease during the past generation. The increased strenuosity of modern life, productive as it is of great numbers of hysterical individuals, neurasthenics, nervous dyspeptics, and the like, is also by its profound effect upon the circulatory and nervous systems and especially upon the emotional balance, a potent factor in the etiology of hyperthyroidism.

Again, the recent world conflict has brought to the attention of the medical profession the revelation of that which was vaguely suspected for a long time, that a sudden change from one's accustomed environments into an atmosphere of complete subordination and servility in the presence of the most intense apprehension and danger to life and limb, as experienced by the raw recruit in the trenches, is not only capable of increasing the activity of the thyroid gland, but has brought into existence thousands of instances of Graves' disease in varying degree in men who probably would have been normal at least so far as the thyroid gland is concerned; and it is this picture of tachycardia, palpitation, tremor, throbbing thyroid, slight exophthalmos, extreme emotionalism, marked prostration, and other typical manifestations, which is frequently erroneously termed shell shock. Yet a third factor may explain the increased number of cases of hyperthyroidism in recent years, and that is the tendency of the profession to change from a state of homogeneity, as represented by the general practitioner, to that of heterogeneity, as represented by the specialist. In other words, as the various branches of medicine become more clearly defined into the various specialties, refinements in diagnostic methods are more apparent, and diseases which have heretofore been erroneously diagnosed are now recognized as indisputable entities.

In passing it may be remarked that since endocrinology is such a broad field of endeavor, and since there are thousands of cases of Graves'

disease still erroneously diagnosed because of the elusiveness or vagueness of the clinical picture, and finally (and this is perhaps the most important reason) since the surgeons and internists are still at odds with respect to whether surgical or non-surgical treatment should be given the preference in the management of hyperthyroidism, the study of the diseases of the thyroid gland and the looming forth into the arena of the thyroid specialist should be encouraged and supported by the profession now more than ever before.

In the presence of the four cardinal symptoms, viz., enlarged thyroid, tachycardia, exophthalmos, and tremor, the diagnosis of Graves' disease offers no difficulty. It must be said, however, that such cases are the exception rather than the rule, at least so far as early instances are concerned. In other words, when the four cardinal symptoms manifest themselves very frankly in a patient, it is a late case, and the prognosis is guarded, to say the least. "The consummation devoutly to be wished" is an early diagnosis, the recognition of the disease in its very incipiency, and this is the greatest argument for the existence of a class of men who should devote most of their time to the study of the thyroad gland in health and disease—the thyroid specialists.

The early recognition of a hyperfunctionating thyroid is one of the most difficult problems in medicine. (The thyroid is not always enlarged, and in women, especially during menstruation or pregnancy, the difficulty is increased by the question as to whether or not a moderate enlargement of the thyroid is physiological only. It is a well-known fact that a state of hyperactivity of the thyroid gland may exist with no apparent increase in its substance. Moreover, exophthalmos usually occurs late in the disease and may for a long time be too slight to attract attention, or it may be unilateral and hence be attributed to another cause. Meanwhile the excess of thyroid secretion in the blood is wreaking havoc with the circulatory and nervous systems. Tachycardia, though quite constant, is often misinterpreted as indicative of "nervousness," hysteria, neurasthenia, "palpitation," nervous dyspepsia, and the like. Not infrequently this symptom and the tremor are also attributed to an excess of tea, coffee, alcohol, tobacco, and occasionally to heredity.

As implied, the thyroid gland may be enlarged or there may be no perceptible enlargement, and there may be varying degrees of goiter. What are the more uncommon local manifestations of thyroid enlargement?

1. Cyanosis, headache, vertigo, and epistaxis may occur from pressure upon the carotid sheath (containing the carotid artery, internal jugular vein, and the pneumogastric nerve). Marked pressure upon the vagus may give rise to phenomena varying with the degree and constancy of irritation.

2. Dyspnea occurs with varying frequency in statistical records, in consequence of the resistance of the underlying muscles and the pretracheal cervical fascia to the gland. This symptom is most marked in instances where the isthmus is greatly involved, or where the latter lies between the trachea and the sternum. Occasionally a unilateral enlargement of the thyroid gland may give rise to dyspnea by the displacement of the trachea to one side.

3. Dysphagia may result from pressure upon the pharynx or the esophagus, and is more common in left-sided goiters for anatomical reasons.

4. Dysphonia with hoarseness, and rarely aphonia, may result from pressure upon the recurrent laryngeal nerve. In my experience, it has often been difficult to distinguish between the dysphonia of nerve pressure and that occasioned by the congestion of the mucous membranes due to pressure upon the trachea.

5. Pulsation and bruit may occur in varying degree, depending upon (*a*) the degree of pressure exerted by the enlarged thyroid upon the carotid artery; (*b*) the extent of the increase in the vascularity of the organ (increase in caliber and number of blood vessels), or both.

A note of caution should be sounded with respect to local manifestations. If the patient is not young and there be pain and tenderness referable to the thyroid substance and the gland is found to be somewhat cyanotic in places, nodular, and the skin closely adherent to the underlying structures, look out for malignant changes!

Occasionally the enlargement of the thyroid is manifested by a mere thickening along the anterior border of the sternocleidomastoid muscle of the right side and is therefore not recognizable, at least in the early stage. This picture is due to the fact that the right lobe of the thyroid is normally larger than the left and is therefore more prone to hypertrophy.

The apparent absence of thyroid enlargement, though there be the other symptoms of Graves' disease to a greater or lesser extent, may be explained by (*a*) the increased functionating of the thyroid without perceptible increase in size; (*b*) pressure, not necessarily by the thyroid, against the cervical sympathetic ganglion, irritation of which gives rise to symptoms closely resembling Graves' disease syndrome; (*c*) an actual enlargement of the thyroid, but of its *inner* surface only and therefore not visible or palpable outwardly (the so-called inward goiters); (*d*) the possible existence of an accessory thyroid, *i.e.* a mass of thyroid substance sometimes occurring in the neighborhood of the tongue, in the larynx, trachea, mediastinal regions, or elsewhere, which has undergone hypertrophy with increased function and is surcharging the blood with thyroid substance.

We have already implied that the tachycardia and the tremor are frequently interpreted as manifestations of hysteria, neurasthenia, chemical toxemias, and inherited tendencies. Occasionally a patient, though not presenting typical manifestations of hyperthyroidism, will begin to behave peculiarly, appear to be markedly changed in disposition within a brief month, and will suffer with melancholia, hysterical outbreaks, or emotionalism, with frequent moments of lacrymation, or, in rare instances, there are outbursts of violent temper with suicidal or homicidal tendencies; a patient of this sort may hastily be classified as a subject of one of the insanities, and a diagnosis of a rare form of the Graves' disease syndrome will not be made until it is too late.

The diagnosis of diabetes mellitus is not infre-

quently made in view of the presence of sugar in the urine in many cases of hyperthyroidism and also in view of the frequent micturition, polyuria, and marked rapid loss in weight and strength. Though diabetes mellitus may sometimes coexist with Graves' disease, this coincidence is rare. The glycosuria of hyperthyroidism is usually not accompanied by acetone; the polyuria is not quite as marked as in diabetes; there is, as a rule, an absence of increased hunger and thirst; the condition here is more acute; there is an absence of the peculiar dryness of the skin and the various skin eruptions characteristic of diabetes; and there is no tendency to visual defects, neuritis, and the various other symptoms typical of the latter disease. On the other hand, the presence of one or more of the cardinal symptoms of hyperthyroidism, discovered on close examination, and the rapid disappearance of the glycosuria on the institution of antidiabetic treatment, serve to make the diagnosis clear.

Many cases of Graves' disease in which marked wasting of the body is the dominant symptom are erroneously classified as instances of incipient pulmonary tuberculosis. This erroneous conclusion is further encouraged by the diminished respiratory expansion, the frequent drenching sweats which may be nocturnal, and the slight rise in afternoon temperature, all of which are commonly seen in exophthalmic goiter. Though here again a tuberculous focus may coexist, where this cannot be demonstrated distinctly by our various diagnostic methods, including examination of the blood, the sputum, and an *x*-ray examination of the chest, tuberculosis may be ruled out. The diagnosis of exophthalmic goiter may be further confirmed by a history of nervous shock or neuropathic tendency, the presence of one or more of the cardinal symptoms of this disease, and the possible existence of an enlarged thymus revealed by *x*-ray examination.

Finally, where the chief symptom in Graves' disease is the tachycardia, it is necessary to differentiate it from the paroxysmal tachycardia which probably has nothing to do with the thyroid gland. Paroxysmal tachycardia occurs at intervals, the pulse is usually more rapid than in Graves' disease (usually about 200 or more per minute), there is usually a sense of great cardiac discomfort and of impending danger, the heart rate becomes suddenly normal within from a few hours to several days, and there is the absence of the typical symptoms of hyperthyroidism.

In conclusion I would say that in view of the fact that the early stages of hyperthyroidism are not typical pictures of Graves' disease, and also because even advanced cases of this disease simulate very closely so many other conditions commonly seen in the practice of medicine that the diagnosis of exophthalmic goiter is difficult and fraught with pitfalls in many instances, it is meet that the diagnostician, when confronted with a patient presenting symptoms which seem to lead to divergent conclusions, carefully and with an unprejudiced mind exclude, if possible, the existence of a hyperfunctionating thyroid before attempting a final diagnosis of the case.

1714 North Seventh Street.

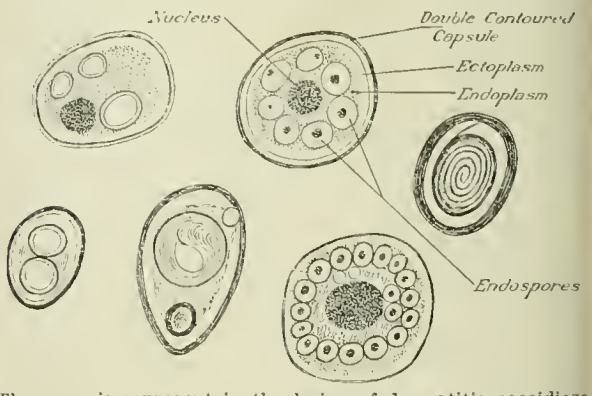
REPORT OF A CASE OF DERMATITIS COCCIDIOSA.

By J. Seilin, M.D.,

Chicago, Ill.

Pathologist, Lake View Hospital.

J. L., male, age 32, cigarmaker, with negative family history, and a personal history of various neurasthenic complaints, married, father of five healthy children, presented himself Nov. 15, 1918, with a lesion of the right palm, about which he related the following details: About nine years previous he first noticed small hard papules on the right palm near the base of the thumb. These would itch intensely at times and would be quiescent at times for varying periods so far as subjective symptoms were concerned. Gradually the papules became larger and fissures and painful ulcerations appeared, involving the proximal one-half of the palm. Deep-seated vesicles that had developed, ruptured, and yellowish pus came out which crusted and later came off, leaving a moist scaling, raw, painful surface with deep cracks and thick hypertrophied edges. Some papules and deep-seated vesicles also remained. Under various skin remedies the condition improved but never healed completely under any treatment, although the patient stated that he had had many different kinds of salves and internal remedies, including hypodermic, intramuscular, and intravenous treatment of the exact nature of which he was ignorant. The disease had been present all the time during the last nine years, with



The organism present in the lesion of dermatitis coccidiosa.

periods of spontaneous improvement and periods of improvement following various lines of treatment, but without permanent result.

The physical examination showed a thin individual, rather under-nourished, a well-marked gastro-enteroptosis, slight hemoglobinemia (80 per cent.), and an eosinophilia of 7 per cent. Otherwise the findings were entirely negative, including the usual laboratory tests of urine and blood, including the Wassermann test. The right palm showed an area about two and a half inches square, near the base of the thumb, presenting a dry scaly condition of the skin, several deep, painful and tender linear cracks, with thick, hypertrophied edges. Beneath the thickened epithelium there shone through about a dozen deep-seated vesicles. Scattered about the lesion were also some superficial abscesses of very small size, and filled with greenish pus. Puncture of these abscesses proved them to be, microscopically, infections with the staphylococcus. The entire lesion was then cleaned with alcohol, and with a sterile safety-razor blade the thick tops of several of the deep-seated vesicles were shaved off. This allowed a clear straw-colored fluid to escape. This fluid, on being spread on a slide and stained with alkaline methylene-blue, revealed a few leucocytes and hundreds of organisms resembling the descriptions of human coccidiosis. They are illustrated in the accompanying drawing. The bodies varied in size from 5 to 25 microns in diameter, and showed a thick, doubly-contoured peripheral membrane. Within was a clear ectoplasm enclosing a granular endoplasm containing from two to ten or more small round bodies resembling spores of a sporozoite,

each containing a deeply-stained, pin-point nucleolus. In the center of the ring of endospores there was a deeply-staining granular nucleus. Some of the bodies contained only one large nucleus, others one large and one small, and others the ring of many described above.

A diagnosis of Dermatitis Coccidiosa was made, and a salve of 1 per cent. copper sulphate in lanolin and petrolatum was prescribed for local application. Internally potassium iodide in ascending doses was also given and hypodermic administration of emetine hydrochloride ½ grain every other day started. The therapeutic results were remarkable. In twenty-four hours the change was like magic and in five days the lesion was healed completely. It should be mentioned that each deep-seated vesicle was carefully laid open by shaving off the top with a sterile safety-razor blade before the patient was sent out of the office. He was again seen six weeks later and no recurrence had taken place and the lesion had entirely disappeared, the palm appearing perfectly normal like the other. He took altogether 3 injections of emetine, ½ grain each, and potassium iodide for about two weeks, attaining a dose of 23 drops t.i.d. at the time of suspending medication.

Comment.—The diagnosis was based on the finding of the protozoanlike organism in the clear fluid from the deep-seated vesicles. In the differential diagnosis other parasitic skin diseases were ruled out by the absence of different organisms. Syphilis was ruled out by the negative Wassermann test, absence of any signs of syphilis elsewhere, and failure of cure by antisyphilitic treatment which he had undoubtedly had, according to his story. None of the organisms showed the phenomenon of budding, so that it could not be classed with the blastomyces, while the clinical picture did not fit in with Darier's disease, Lupus vulgaris, palmar psoriasis, or chronic eczema.

In 1891, Wernicke reported a case with cutaneous lesions containing a large number of sporozoites, and up to 1896 it was the only case of protozoan-dermatitis reported, when Gilchrist reported two more cases observed at Johns Hopkins Hospital. These were fatal cases of generalized coccidiosis, including skin lesions, and the gross and microscopical pathology is beautifully described and illustrated. In 1904, Ophüls and Wolbach showed that the organism was not a protozoan sporozoite, but a yeast organism closely related to the blastomyces. The life cycle of the parasite was described by the latter in the same year. Lipsitz, in 1916, reported a case of fatal bronchopneumonia caused by the organism, and he agrees with Ophüls as to the probable classification of it with the blastomyces. A nodule from his case was cultured by Klenk on glycerin and plain agar, and in the older cultures aerial hyphae developed at the edges. The growth consisted of mycelial threads with club-shaped endings. Injection of material from these cultures into a guineapig produced subcutaneous nodules, and later abscesses containing many doubly-contoured bodies similar to those of the culture and those found in the patient's lesions. Lipsitz mentions that his patient was a heavy smoker. My patient was a cigarmaker, and rolled the tobacco with the palm of the hand involved.

Summary.—1. This case was one of a purely localized dermatitis for nine years, with periods of spontaneous improvement and exacerbations, and caused by a parasite resembling a protozoan sporozoite, in that it reproduces by endospore formation, but probably belongs to the hyphaemycetes, because it produces aerial hyphae in cultures.

2. It responded promptly and completely to local applications of 1 per cent. copper sulphate ointment and internal administration of potassium iodide with hypodermics of emetine hydrochloride.

FIVE RECENT BRONCHOSCOPIC AND ESOPHAGEAL CASES.

By JOSEPH EASTMAN SHEEHAN, M.D.,
NEW YORK.
INSTRUCTOR IN DISEASES OF NOSE AND THROAT IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING EAR SURGEON TO ST. MARY'S HOSPITAL AND PORT JERVIS HOSPITAL, PORT JERVIS, N. Y.

QUITE twenty years have gone by since Killian of Germany demonstrated to the world the feasibility of removing a foreign body from a bronchus or the esophagus. Since that time it is very interesting to trace the growth of esophagobronchoscopy, particularly during the past eight years. Previous to this time the profession was reluctant to admit that the respiratory tube and the esophagus could be readily and safely examined. Before the introduction of esophagobronchoscopy the mortality of inhaled and swallowed foreign bodies was extremely high. A review of the literature amazes one, indeed, at the high mortality previous to the introduction of this new branch of surgery. Killian's demonstration was one of the great events in surgery. It has been the means of saving many lives.

Esophagobronchoscopy is not a dangerous procedure if performed by one who has an intimate knowledge of the throat, esophagus, and lungs, and is skilled in handling the instruments. Great gentleness is the watchword, along with untiring patience and manual dexterity. So many laryngologists have now acquired the art of bronchoscopy that accidents which formerly happened are indeed few. The accidents which now may occur are not usually due to any improper manipulation of the instruments, but depend more upon the nature, position, size, and length of time which the foreign body has been swallowed or inhaled. For example, the removal of a foreign body with a rounded surface, like a coin, from the esophagus, would be very much less dangerous than that of an open safety pin with the point upward. The removal of a pin deep down in one of the bronchi would be more dangerous than removing one higher up.

Nothing can be gained by hurrying in one's work. It must always be borne in mind that the patient is much safer with a foreign body in the esophagus or air passages than he would be if it were ruthlessly torn out. The great temptation after locating a foreign body is to grasp it immediately and remove it at all hazards. Rarely is it necessary to remove a foreign body immediately. It is always better to desist from any procedure

until the case has been thoroughly studied from all angles.

If performing bronchoscopy for diagnostic or therapeutic purposes in adults, the application of 10 per cent. solution of cocaine to the pharynx, base of the tongue, and larynx renders the patient quite tolerant of the instrumentation. This is also true of the removal of foreign bodies. It is well to give 0.016 of morphine sulphate hypodermically twenty minutes before the manipulation. This renders the patient less intolerable of cocaine and reduces its toxicity.

It is always desirable to use no anesthetic in children when removing foreign bodies from the esophagus or air passages, up to the eighth year. The determining factors whether ether is to be used will be the position, place, size, and nature of the foreign body.

Case I.—Catherine G., 7 years, Bayonne, N. J., was admitted to the Babies Ward of the Post-Graduate Hospital August 29, 1918, with a history of having swallowed a safety pin seven days previous. This was followed by sternal pain and fever. The pain continued for two days. There was no difficulty in swallowing fluids, but the intake of solid food would produce sternal pain. A roentgenogram taken by Dr. Meyer of the Post-Graduate Hospital, located the safety pin of medium size in the esophagus about the level of the bifurcation of the trachea, with its point perforating

1. 2. 3. 4.

Foreign bodies extracted from the esophagus and air passages.

the esophageal wall and directed downward, forward, and to the right. (See illustration, 1.)

August 31, 1918, under a very light ether anesthesia, an esophagoscopy was performed by me. I immediately came down on the foreign body, the location of which verified the roentgenogram. It had perforated the esophageal wall. The point of perforation looked angry and black and there was thrown around it an elevated mass of fibrin, nature's way of closing it. I manipulated the esophagoscope in such a way that the ring of the safety pin entered the tube. I then introduced a pair of Pfau forceps and it was an easy matter to extract it. A 10 per cent. solution of argyrol freshly prepared was painted over the site of the perforation. The child left the hospital within four days entirely well.

Case II.—Philip B., age 4 years, was admitted to the orthopedic ward of the Post-Graduate Hospital, July 16, 1918, with the following history. While playing on the floor the mother noticed the child put a pin in its mouth. This was immediately followed by violent coughing and gagging. The family physician was called and after examining the child saw the pin in the lower part of the throat. After several unsuccessful attempts at removal, he lost sight of the pin and sent the child to the hospital. A roentgenogram was made by Dr. Meyer of the Post-Graduate Hospital and located the pin, point upward, partly in the larynx and partly in the trachea. (See illustration, 2.) The afternoon of the same day I attempted to remove it by bronchoscopy, without an anesthetic. After passing the bronchoscope excessive secretions from the lungs filled the tube of the instrument to such a degree that its removal was necessary. This happened twice again. The child became so cyanosed, I desisted from any further manipulation that day.

The following day, under a very light ether anesthesia, I again bronchoscoped the little patient. After passing between the vocal cords and examining the upper part of the trachea, I was unsuccessful in locating the pin. I now performed a lower bronchoscopy and was immediately rewarded. The pin had travelled down to the bifurcation of the trachea, lying crosswise to the tube over the bridge. After cleaning out the tube very carefully and mopping all secretions from the area surrounding the pin, I grasped the head of it with a pair of Jackson forceps and removed the pin with ease.

Case III.—James L., South Orange, N. J., consulted me July 10, 1918, giving the following history. Two days previously, while hanging curtains, having in his mouth several eyescrews, he suddenly slipped and fell from a ladder about three feet high. He knew he had swallowed one of the screws, as he complained of difficulty in breathing, sternal pain, and a persistent cough, which kept him awake at night. These symptoms immediately followed the fall.

I anesthetized his pharynx, base of the tongue, and larynx with a 10 per cent. solution of cocaine. Twenty minutes before the bronchoscopy, morphine sulphate 0.016 was given hypodermatically. Upper bronchoscopy revealed nothing. After a lower exploration, the screw eye could be seen almost choking the entrance of the right bronchus. I grasped it with a long pair of Jackson forceps and removed tube, forceps, and screw together. (See illustration, 3.)

Case IV.—Mary L., eight years of age, was referred to me September 10, 1918, having swallowed a safety pin. The child insisted that the pin was sticking into her throat. Without an anesthetic she was placed in Jackson's "low head" position and a medium size laryngoscope was inserted. The safety pin which was of a large size could be seen with its point entering the esophagus. (See illustration, 4.) With a pair of straight throat forceps it was easily removed.

Case V.—Ida B., age 28, an idiot, was admitted to the ward of the Post-Graduate Hospital with the statement that she had swallowed a fish bone four days previous. She was emaciated and in great pain as she could swallow neither food nor fluids. She was taken to the operating room the following day and esophagoscoped by me. She was placed in the Killian supine position and Brünning tubes were used.

After examining the upper esophagus very carefully, as I pushed the tube toward the stomach, with great satisfaction located the bone well down the esophagus, a little above the hiatus. The esophageal wall was somewhat lacerated in this area and looked ugly. After passing my grasping forceps through the tube, I lost sight of the bone. Repeated attempts by myself and others resulted in failure. The lacerated wall was then painted with a freshly prepared 10 per cent. argyrol solution.

The next day the patient was greatly improved and although she was able to swallow light food and fluids, I again esophagoscoped her. Again I failed to locate the foreign body. Undoubtedly in our first manipulation we pushed it along into the stomach. The walls were again painted with a 10 per cent. solution of argyrol.

For four days after she was given 0.26 crystals of argyrol in water three times daily. She left the hospital entirely well after the fifth day.

24 East Forty-eighth Street.

Unilateral Gynecomasty after Injury to the Testicle.—Anert and Declety relate the following curiosity of medicine: A soldier, aged 25, was wounded in the scrotum in October, 1917. In the following March he was found to have a right breast agreeing in all respects with that of a young girl at the beginning of puberty. Investigation showed that the right testicle had been involved in the injury. Such behavior has been known to follow only mild lesions of the testis—never severe traumatism or total destruction or castration. The precise mechanism cannot be comprehended but both the nervous and endocrinic systems must be involved.—*La Presse Médicale.*

Medicolegal Notes.

Vaccination of School Children.—Certain infant complainants brought suit to enjoin the authorities, including the local board of health of Granite City, Ill., from preventing the complainants from attending the public schools unless they were first vaccinated, according to a resolution adopted by the board of health. When the resolution was passed and enforced smallpox was epidemic in Granite City.

The question of the right to require school children to be vaccinated as a prerequisite to their admission to the public schools has met with frequent discussion in the various jurisdictions of this country. There is a manifest lack of uniformity in the decisions of the courts. In Illinois the rule is firmly established that school directors and boards of education have no authority to exclude children from the public schools on the ground simply that they refuse to be vaccinated, unless in cases of emergency, in the exercise of the police power, it is necessary or reasonably appears to be necessary to prevent the contagion of smallpox.

But in cases where there is an epidemic of smallpox the exact question here raised seems never to have been passed on directly by the Illinois Supreme Court. It is not a new one, however, in other jurisdictions having similar health laws. The courts are practically a unit in holding that in the event of a present or threatened epidemic such rules and regulations as are now under consideration are reasonable and should be upheld; and such has been the rule in states where there has been no express authority requiring vaccination. Where smallpox is epidemic, it is not a necessary prerequisite to requiring vaccination that pupils have been personally exposed. It has been held in some jurisdictions (including Kentucky, Minnesota and Utah), that even without specific authority from the Legislature or city council, local boards having control of schools or of the general care of the public health are justified by the existence of the emergency in making vaccination a condition for admission to the public schools. The Illinois Supreme Court, in Potts v. Breen, 167 Ill. 67, 47 N. E. 81, 39 L. N. A. 152, 59 Am. St. Rep. 262, while making no direct decision upon the point, recognized the rule that in cases of emergency, when necessary or apparently necessary to prevent the spread of smallpox and preserve the public health, pupils may be temporarily excluded from the public schools unless they are properly vaccinated or have had smallpox.

The resolution of the board of health was held reasonable in view of the fact that smallpox was epidemic. The board had ample statutory authority to pass the resolution. It was not a permanent rule or law, but a mere temporary order set in force for a limited time (two weeks), as a means of stamping out the disease and preventing its spread. No one was compelled to be vaccinated. The simple effect of the order was that no child could enter the school unless vaccinated while the rule was in force. As it was the duty of the board of health to enforce such reasonable rules and regulations as would stamp out the epidemic and promote the public health and the resolution seemed well calculated to accomplish that purpose, and as a public necessity existed for such action, the board of health must be held to have acted legally in passing the resolution and the school board in enforcing it and requiring vaccination as a condition to pupils entering the schools. The exercise of such authority by the board of health and the school board finds ample authority in the police power of the state when such a necessity arises, as is shown in this case, and no constitutional rights of the children were violated. No child has a constitutional right to carry to others in school the loathsome disease of smallpox. Vaccination is now recognized as the only safe prevention of its spread. It is approved by medical science generally, and by governmental authorities throughout the civilized world. In many countries compulsory vaccination has become the settled policy of the state, and our own country has adopted it as one of the preliminary requisites to military service. A child infected with smallpox may communicate the disease to hundreds of others, and the disastrous results therefrom are incalculable. Where smallpox is epidemic, and a large number of cases are actually existing in a city, or community, no one can tell at what moment some person may become exposed and break out with the disease. By the teaching of the best medical authorities, a person who has been thoroughly and successfully vaccinated will be entirely immune from the disease, or put in such condition that if he should contract the disease it would only be in the very mild form commonly known as varioloid, which rarely causes scarring or fatal results. In other words, the result of vaccination, according to such authorities, is not only the arrest of the spreading of the disease, but the prevention of fatalities among those who are actually exposed to the disease, and who contract it in its mildest form. While, on the other hand, it is true that occasionally very disastrous results happen from the use of impure vaccine, and there are many people, for that or other reasons, who resist, and (the court holds) have the right to resist, compulsory vaccination of their children except in cases of necessity, yet they have no right to insist on their children continuing in school and mixing in large congregations without obeying such requirements when smallpox is epidemic in the community, and such children, perhaps, have been exposed to it. The right to enjoy school and other privileges, recognized by our law, must be so used and enjoyed as not to expose other people unnecessarily to dangerous diseases or contagions. The police power is broad enough to protect all citizens against such exposure, and it is not an unreasonable requirement to prevent children from having the benefits of school unless vaccinated, etc., under such conditions as existed in Granite City, when the resolution of the board of health was passed, and particularly when such exclusion was only for two weeks, and with the privilege to the children to remain unvaccinated by remaining out of school for such time.—Hagler v. Larner, Illinois Supreme Court, 120 N. E., 575.

Expert Evidence—Smoking Opium.—In a prosecution for illegally manufacturing smoking opium an expert chemist and analyst employed by the Commissioner of Inland Revenue was permitted to testify as to the manner by which Chinese smoking opium could be distinguished from domestic opium, as to the average morphine content of imported smoking opium, and as to the average morphine content of domestic smoking opium; that where gum opium is manufactured into smoking opium the morphine content is increased from 50 to 100 per cent. and that the smoking opium analysis made by the witness was made of domestic gum opium, and not of opium made in a foreign country.—Lee Mow Lin v. United States, C. C. A., 250 Fed. 694.

Insanity as a Defense in Criminal Cases.—One charged with homicide testified that he had been drugged and robbed by the deceased a few days before the allege homicide, and that he was unconscious of any act that he did from the time he was so drugged and robbed until after the homicide, when he found himself in jail. The West Virginia Supreme Court of Appeals held that there was evidence tending to support the defense of insanity at the time of the commission of the homicide, and an instruction presenting this evidence to the jury should have been given. The court said that it might be that the defendant's conduct was entirely inconsistent with his contention; but since a party accused of crime is permitted to testify in his own behalf, the jury alone must say what faith should be given to his statements. The court followed what is known as the right and wrong test, or the ability to distinguish between right and wrong. This rule is very satisfactorily stated in the leading English case known as McNaghten's Case, where it was said, in regard to the effect of insanity as affecting responsibility in criminal matters, that the jurors ought to be told in all cases that every man is presumed to be sane, and to possess a sufficient degree of reason to be responsible for his crimes, until the contrary be proved to their satisfaction. To establish a defense on the ground of insanity, it must be clearly proved that, at the time of committing the act, the party accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know, that he did not know he was doing what was wrong. Failure to give the instruction was held reversible error.—State v. Alie, 96 S. E. 1011.

Military Medicine.

AVITAMINOSES IN THE ARMY.

Bruntz and Spillman, writing in *Le Progrès Médical* for January 11, consider this subject very exhaustively. By controlling clinical experience with feeding experiments on animals important discoveries seem to be in the making. Thus it may be possible to bring trench foot under the rubric of a deficiency disease. The subject matter is considered under eight heads. The first section deals with generalities in connection with vitamines, and contains nothing new. The quantity necessary for life may be infinitesimal, but since a certain amount of sterilization will destroy them the most abundant and best balanced ration could be denatured by excessive cooking and preserving processes. Artificially prepared vitaminiferous substances quickly suffice to remedy the deficiency diseases, and are therefore of diagnostic value. The authors mention but two types of deficiency disease, viz., scurvy and beriberi. Such simple and available remedies as beer yeast and lemon juice suffice to make good the severest types of deficiency.

The second section is devoted to the richness of the soldiers' rations in vitamines. These comprise fresh, frozen, tinned, and preserved meats and fish, bread, vegetables, fats, coffee, wine, etc. Which of these foods are vitaminiferous? Meats, both fresh and frozen, breads not made of white flour, potatoes, lentils and lima beans, and new wine. Which are free from vitamines? All tinned, smoked, and salted provisions, sterile milk, and decorticated grains of any kind. The effects of heat must now be added. Foods apt to be damaged by overcooking are roasted and boiled meats and beans, etc. Anything cooked to a crust, whether meat, bread, or vegetable, is damaged as to its vitamine content. Since it is extremely difficult to draw a line here, underdone food, when digestible, must have precedence. The men who have been fed for days on preserved foods rush with avidity upon raw carrots and turnips and unripe fruit when nothing else avails. No scruples stop them in this quest. There is also an instinctive repugnance to foods which contain no vitamines, such as decorticated rice. This is so common as to suggest a physiological defense reaction.

The third subject for consideration is clinical avitaminosis, but this is quickly dismissed because all are familiar with the phenomena of scurvy, Barlow's disease, beriberi, and pellagra. Next to be considered is experimental avitaminosis. No original work is mentioned, but there is a résumé of the recent finds of Weill and Mouriquand. It is demonstrable that two types of deficiency disease can be genorated in the same animal at the same time, and this has also been confirmed in human pathology, as cases of associated scurvy and beriberi have been reported.

The fifth section is devoted to the relationship between trench foot and deficiency in vitamines. Certain factors in the genesis of the former are cold and moisture, compression, maceration, neuritis, infection, etc. Interest centers around the element of neuritis—one whose activity seems assured. This is recognizable in animal experiment in which it is able to cause edema. Mild neuritis may also exist without trench foot. The cause of the neuritis is evidently internal, and to a large extent the latter may be regarded as the parent lesion, the others being contributory. The differential diagnosis between trench foot and simple frostbite has long been possible, and different degrees of cold are required to produce the two. Trench foot has been seen outside of the trenches. There is some evidence to show that rice-eating Arabs suffered more promptly and severely than Europeans on regular rations. Trench foot has actually been seen in the warm months, and could then be readily explained by diet. The Japanese had peripheral neuritis before Mukden, which was, of course, frankly called beriberi. The relation of trench foot and edema from underfeeding has not yet been traced.

Sixth, the authors consider all of the war maladies which could possibly be classed as wholly or in part avitaminoses. There are many such, some local and others constitutional, which yield to treatment with vitaminiferous foods. To include everything which is benefited by the lactovegetarian regimen is, however, to go too far. Under the seventh head, prevention, the authors say that the two localities to be kept under observation constantly are the buccal cavity and the feet, while at the same time the diet must be carefully supervised both as to content and degree of cooking. Under actual treatment, the extracts which contain vitamines from whole rice, etc., and foods rich in the same, should be given. Finally, the authors assert that they have not the least doubt that trench foot is essentially an avitaminosis.

Announcement of the Volunteer Medical Service Corps.—The Council of National Defense has sent to each physician in the United States, exclusive of those who served in the Medical Corps of the Army for the past two years, and members of the Voluntary Medical Service Corps, a communication requesting that he fill out and return promptly to the Washington office an accompanying questionnaire, so that there might be on file in Washington complete individual information covering the members of the profession. Simultaneously with the distribution of these questionnaires, State and county representatives of the Voluntary Medical Service Corps were instructed to urge all doctors in their communities to comply promptly with the request of the Council to fill out and forward promptly to Washington the blanks sent them, and to advise those who by any chance failed to receive blanks to communicate with the Council of National Defense at once in order that application blanks might be furnished them. These records, upon their completion, will be transferred to the Surgeon General's Library, where they will be kept up to date by a force assigned for the purpose, and be accessible to all government bureaus. Every physician is requested to cooperate with the Council on National Defense in making this record complete.

To Consolidate Care of Wounded Soldiers.—A bill introduced into the Senate on February 18 by the Senate Building Committee provides for a consolidation of the work of caring for incapacitated soldiers under the Public Health Service and the War Risk Insurance Bureau, with army hospitals

turned over to the Public Health Service as needed. This consolidation can be arranged for so as to provide for 19,000 patients at a cost of $7,100,000, whereas, with authority for the work divided, buildings and equipment for the care of 5,000 patients would cost $12,000,000. Delivery to the Public Health Service of the Chicago Speedway Hospital was provided for upon the payment of $2,500,000 to the contractors. This hospital was started last summer, with the expectation that the War Department would pay this sum, but the contract was never approved by the department. The bill also provides an appropriation of $1,500,000 for the construction of a hospital at Dawson Springs, Ky., on a site donated to the government; $900,000 for the construction of a new hospital at Norfolk, and $190,000 for extending the hospital facilities at Stapleton, S. I.

Health of Home Troops Good.—A report issued by the Surgeon General's office under date of February 21 states that there were no epidemics in home camps during the week of February 14. There are in the camps only scattering cases of influenza.

War Community Service for Convalescent Officers.—The New York War Camp Community Service announces that a Convalescent Bureau has been opened at Madison Avenue and Forty-fourth Street the object of which is to offer to any officer of the United States Army, Navy, or Marine Corps, on furlough, or after discharge from the service, every facility for rest and recuperation in the country. Hospitality is offered in private homes at moderate prices, and special rates have been secured at out-of-town hotels and country clubs.

Captain Gouverneur M. Phelps, M. C., U. S. Army, of New York, who has worked on all battle fronts except the Italian, arrived home recently on the transport *Meraukee.*

Officers of Post-Graduate Unit Arrive.—Officers of the Post-Graduate Hospital Unit of New York, which left this city in August, 1917, returned on the *Manchuria,* on February 22. Among those aboard the vessel were Major James A. Martin, Major John Connors, Captain P. Knapp, and Lieut. James T. Sullivan. Lt.-Col. Samuel Lloyd, who was in command of the unit, is still in France. These officers report that at the hospital at Savenay they cared for about 67,000 men, about nine-tenths of whom were suffering from wounds.

Influenza Epidemic on Transport.—The transport *Manchuria,* arriving in New York on February 22, had aboard 4,248 returning soldiers when it left Brest. Two days after sailing an epidemic of influenza appeared, and 168 men came down with the disease, 24 of them developing pneumonia, and four died.

Death Rate in Army from Battle and Disease.—Statistics recently made public by General March, and prepared by the General Staff, reveal the fact that the battle death rates during the war exceeded the death rate from disease. The battle death rate for the entire American army in this war was 20 per thousand per year. In the Expeditionary Forces it was 57 per thousand per year. The disease death rate was 17 per thousand per year in the Expeditionary Forces and 16 in the army at home. This table shows that the battle death rate among the American forces was only half that of the British Expeditionary Forces, which is given as 110 per thousand per year. General March, in commenting on these death rates, expresses the belief that the decreased death rate from disease was due first to the inoculations, and second to the efficient work of the medical corps. Had it not been for the influenza epidemic the disease death rate would have been only half what it was.

Illness Among the Troops at Brest.—In a recent report to the Senate Military Committee, Major Samuel W. Ellsworth of the Medical Corps, who has recently returned from France, stated that many returning American soldiers were dying of disease at the debarkation camp at Brest after coming from the front line in good condition. He attributes this high mortality to the unsanitary condition of the camp, due to damp weather and overcrowding. United States Senator Robert L. Owens, who has just returned from France, has declared his intention of urging Secretary Baker to take action looking to the relief of these conditions immediately.

Deaths in the Service.—Capt. Thomas Hundley Seay, M. C., U. S. Army, of Laurel, Miss., a graduate of the University of Nashville, Tenn., in 1906, a member of the State Board of Health, on duty at Fort Oglethorpe until his discharge from the service a short time ago, died at his home from pneumonia following influenza, on January 15, aged 36 years.

Lieut. William John Davison, M. C., U. S. Army, of New Castle, Pa., a graduate of the Medico-Chirurgical College of Philadelphia, in 1905, on duty at Debarkation Hospital No. 3, New York City, died there recently from pneumonia at the age of 35 years.

Lieut. Edward Lewis Rochfort, M. C., U. S. Army, of New York City, a graduate of the Medical Department of Yale University, in 1912, an instructor in the United States Government Neurological School No. 1, New York City, died of influenza in that institution on January 26, aged 28 years.

Major Albert George Bising, M. C., U. S. Army, of Weehawken, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1896, on duty with the American Expeditionary Forces in France, died from pneumonia in Toul, France, on November 2, aged 48 years.

Capt. Samuel McAllister Mauney, M. C., U. S. Army, of Earl, Ark., a graduate of the University of Tennessee, Nashville, in 1914, on duty with the American Expeditionary Forces in France, died at Nantes, France, on November 1, 1918, from pneumonia, aged 27 years.

Lieut. Charles Arthur Robertson, M. C., U. S. Army, of Hopkinsville, Ky., a graduate of Vanderbilt University, Nashville, Tenn., in 1917, aged 24 years, on duty with the American Expeditionary Forces in France, died on November 14 from lobar pneumonia following wounds received in action.

Lieut. Albert Marinus Larson, M. C., U. S. Army, of Jasper, Minn., a graduate of the University of Minnesota, in 1917, aged 29 years, on duty with the American Expeditionary Forces, died in American Red Cross Military Hospital No. 24, Moseley Hill, Liverpool, England, on October 13, 1918, from pneumonia.

MEDICAL RECORD.

New York, March 1, 1919.

ACUTE DILATATION OF THE STOMACH.

THE earliest authoritative account of this condition in English was published by Fagge in 1873. Previously, cases had been reported by Rokitanski, in 1842; by Miller and Humby, in 1853; by Bennett, in 1856, and by Wilks, in 1857. Campbell Thomson, in 1902, published an analysis of forty-four cases collected from the literature. Since then there have been a moderate number of cases reported in various parts of the world, especially in France, Germany, and America; yet the condition has been regarded as very rare. However, it is not likely that the condition is nearly so rare as the meager reports to be found in the literature would make one believe; rather it is likely that the condition is not recognized, and that many patients have been considered to have died from postoperative "shock" or from intestinal obstruction, when the actual pathological condition was acute dilatation of the stomach.

Doolin, who has seen two cases of acute dilatation of the stomach, contributed a very valuable article on this subject to the *British Journal of Surgery* for July, 1918. In this he refers to the very meager amount of information to be obtained from the textbooks, especially as to what he finds the most successful method of treatment. His article is based upon the reports of 188 cases which he succeeded in collating from various sources. Of these 188 cases, 133 (nearly 69 per cent.) occurred after operation, and fifty-five without any previous operative interference. As Doolin says, the postoperative group is of exceeding interest. The condition followed abdominal operations in ninety-six cases, of which forty were gynecological, twenty followed operations on the gall-bladder, eighteen followed operations on the stomach and duodenum, eleven followed appendectomy, and five followed herniotomy. Of the extraabdominal operations, seven were upon the kidney, six upon the thorax, thirteen upon the extremities, and one upon the face. Apparently in twelve of the reports the site of operation was not stated.

In the nonoperative group acute dilatation occurred under many conditions. In a fairly large number of cases it followed the ingestion of large quantities of food; while in ten cases it was associated with spinal deformity. It has also occurred in the course of long continued fevers, such as typhoid, or of acute infectious diseases, such as pneumonia. Among other less commonly associated conditions there are mentioned phthisis, injury to the abdominal wall, and confinement. Finally, there was an extremely remarkable group where acute gastric dilatation arose suddenly in perfect health, without any explanation whatever; in one case the condition started "in a hearty laugh."

Doolin finds that over 60 per cent. of the cases occurred in women; that it may occur at any age, but is most frequent between the ages of twenty and forty; that the youngest case was that of a breast-fed infant nine months old; and that the oldest case was that of a man of eighty-six, who was admitted to the hospital for intracapsular fracture of the neck of the femur, and who died within half an hour after taking a glass of milk, the diagnosis in the latter case being made at autopsy. After a study of the various hypotheses as to the causation of acute dilatation—and we may say, in passing, that the etiology of acute gastric distention is still shrouded in mystery, Doolin takes up at considerable length the symptoms, post-mortem appearances, prognosis, and treatment. He finds that the most prominent symptoms are vomiting, distention of the abdomen, and collapse; others being pain in the epigastrium, tenderness over the distended stomach, respiratory embarrassment, visible peristalsis, thirst, and scanty urine. The bowels may be loose or constipated. The initial symptom, as a rule, is epigastric pain. Vomiting occurs early in over 90 per cent. of the cases, but gives no relief. As the author says, "The fluid seems to well up, frequently accompanied by volumes of gas." The vomitus is watery, at first yellow or green, due to the admixture with bile, later dark brown or black, due to the admixture with blood. The vomitus may be of sour offensive odor, but is never feculent; and the quantity is often amazing. Distention develops rapidly; is manifest first in the epigastrium and gradually extends downward to and beyond the umbilicus, in some cases reaching even to Poupart's ligament. The distended stomach occupies the *left* side of the abdomen, the right side being very little affected. Pain varies in severity, but is exacerbated by the occurrence of visible peristalsis, the patient sometimes screaming aloud with the intensity of the cramping, vise-like pain. Pain is rarely altogether absent. Thirst seems to be a very constant symptom, and is sometimes so great as to be almost unbearable, in spite of infusions, enemata, or drinking. The enormous amount of fluid that is expelled from the stomach accounts for the scantiness of the urine, which may amount to almost total suppression. There is no particular rise in pulse rate or temperature in the early stages. Later there is always rise in pulse rate, but still without any rise in temperature. Respiration rate increases proportionately with the embarrassment due to pressure up through the diaphragm. Hiccough is an uncommon symptom. A few other uncommon symp-

toms, such as dilatation of the superficial abdominal veins, are mentioned.

In discussing the prognosis and treatment, Doolin calls attention to the fact that an acutely dilated stomach manifests little or no tendency to spontaneous cure, and remarks that practically all the untreated or unrecognized cases terminated fatally. During the past ten years there has been an improving prognosis, due to the adoption of better methods of treatment. Thus, statistics compiled in 1907 showed a mortality of 72 per cent.; in 1908, of 63 per cent.; in 1913, of 54 per cent. There are four methods of treatment; and, as Doolin says, "We get a truer perception of the patient's chances if we analyze the mortality of the various methods of treatment adopted:

1. Of 31 cases treated medically, 29 died.....93%
2. Of 29 cases treated by operation, 21 died.....72%
3. Of 54 cases treated by lavage, 25 died, nearly.....50%
4. Of 30 cases treated by posture, 2 died, nearly..... 7%

Thus, of 114 cases where postural treatment was not carried out, seventy-five died, giving a combined mortality of 65 per cent; whereas in the thirty cases where postural treatment was adopted, the mortality is reduced with a jump to below 7 per cent."

Since practically nothing is to be expected from purely medical treatment, it is idle to discuss it. Regarding purely surgical treatment, Doolin finds that five different procedures were carried out with the following results: Gastrotomy, with evacuation of the contents of the dilated viscus, was carried out in six patients with five deaths; gastrostomy was employed on seven patients with six deaths; gastroenterostomy was carried out seven times with four deaths; jejunostomy was fatal in the one case tried; exploratory laparotomy was performed eight times and the dilated stomach emptied by tube or manual compression, with five deaths. The statistics of the treatment by lavage have already been given. Regarding postural treatment, attention is called to the fact that the adoption of the prone position was first recommended by Schnitzler of Vienna in 1895. The technique is as follows: "The method is simplicity itself: the patient is turned over on the abdomen, with a large pillow beneath the pelvis, and the foot of the bed elevated; thereby the fluid which has collected in the lowest portion of the stomach is displaced upward by gravity; the fluid is then more easily evacuated out of the stomach, and relief is given from the downward drag of the loaded stomach on the intestine: the essential feature of this position is the relief it affords from the mechanical obstruction of the duodenum." Researches on experimental ileus have shown the importance of the earliest possible replacement by saline solution of the tissue fluid lost by vomiting; hence Doolin recommends, in addition to the early use of the tube and prone position, the free injection of saline solution in these cases of acute gastric dilatation. With earlier recognition of the condition and the routine employment of the above resources, the mortality of acute gastric distention should be markedly decreased.

CARDIAC COMPLICATIONS OF INFLUENZA.

Influenza when in a virulent form, or, perhaps, it may be more correct to say when the disease is complicated with pneumonia, almost inevitably involves the heart. Consequently, when a medical man is called in to treat influenzal pneumonia he adopts frequently a routine treatment of stimulating the heart. What then are the cardiac complications of influenza and to what are they due?

Sir James Mackenzie deals with the question in the *Practitioner* for January, 1919, and states that the cardiovascular phenomena in serious cases are the same as in other severe cases of infection. The picture of an individual suffering from a severe attack of influenza complicated by pneumonia is not really one of heart disease, but of intense intoxication of the cardiac system. The reason why Mackenzie refers to this general intoxication as being the true source of danger is that in treatment, when the diagnosis seems to point to a particular organ as at fault, remedies are all directed to that organ, and it is often stated that the patient died of heart failure, in spite of energetic therapeutic treatment. As a matter of fact, it may be gathered from the post-mortem study of the heart in such cases that the myocardium is so extensively damaged that it is useless to inject strychnine, caffeine, or oil of camphor. Mackenzie holds that these drugs are incapable of affecting the heart in health, let alone when in the grip of a severe poison, and for this reason, he holds, drugs of the digitalis group are also useless. Moreover, Mackenzie says that he has never seen any case of influenza in which damage was limited to the heart alone, such as occurs in rheumatic fever. In the treatment of severe cases he says there are no remedies of value so far as the heart is concerned, and the only hope is to employ such aids as will tide the patient over a serious crisis. If the patient is the host of some microbe, the treatment should be devoted to increasing his power of resistance. If he is poisoned, treatment should be devoted to the elimination of the poison. Should certain tissues be injured, then treatment should be devoted to their healthy renewal.

As for exercise in heart affections, Mackenzie points out that there is a notion deeply rooted that, if there is anything wrong with the heart, the patient must be restricted in the amount of effort. He, on the contrary, recommends gentle exercise, out of door exercise, as soon as possible after the fever has subsided. In advising this course, he wishes to improve the mental outlook of the patient as well as better his physical condition. In order to brace up the spirits of those suffering from cardiac disability following influenza, exercise of a pleasurable kind or occupation of an interesting nature is recommended. The notable feature of the paper is that in the opinion of this great authority on heart disease cardiac stimulants are of no avail in the treatment of severe influenza. This conflicts with the views of many, and probably the advice not to treat the heart symptoms by themselves will not be widely followed.

HYDATID CYSTS OF THE URINARY BLADDER.

Hydatid cysts of the urinary bladder coexist frequently with cysts of the same nature in other viscera. They have been known to attain the size of an apple or even larger, in one instance the cyst extending upwards above the umbilicus. Their rounded shape, smooth surface and contents do not differentiate them from hydatid cysts of other structures and they invariably contract rather close adhesions with the surrounding organs which they compress. Among the organs involved in cases of hydatid cyst of the bladder the rectum comes in for the largest share, and like the bladder, its functions are interfered with and this may afford the first clinical evidences of the presence of a growth in the pelvis. The majority of writers on this subject agree in the belief that these cysts are more prone to develop in subperitoneal connective tissue surrounding the bladder, but Legueu maintains that in one case the cyst had an extraperitoneal development.

These cysts develop slowly and as they increase in volume they decorticate the serous membrane and become intimately adherent to the walls of the bladder. Occasionally the adhesions are so intimate that one might be led to suspect that the cyst originated within the bladder, but the requisite condition for proving an intravesical origin must be the presence of muscular fibers of the same type as those of the bladder on the internal aspect of the cyst.

The onset of these cysts is generally insidious and disturbances in micturition are the first clinical manifestations of the process. These consist of frequency and difficulty in voiding urine, while complete retention may also arise. Rectal disturbances, such as difficult defecation or constipation do not usually arise in the early stages of development of the cyst. A sensation of weight in the perineum is most usually complained of and an examination will reveal a rounded, smooth tumor with little mobility on account of adhesions with the surrounding structures. When a catheter can be passed an obstacle will at once be detected in the region of the prostate, but when the instrument cannot be made to enter the bladder, which has been known to occur in some instances, the diagnosis may offer considerable difficulty. Hydatid thrill and exploratory puncture will prove the true nature of the tumor. After the cyst has attained a certain size all the symptoms to which it gives rise become more accentuated. Constipation increases, pain becomes more prominent, and the urine is voided in various ways, sometimes by an exaggerated pollakiuria. Autopsies have revealed dilatation of the ureters and renal pelvis, as might be expected, and this, of course, darkens the prognosis which depends very largely upon the patient's general state of health.

Treatment is naturally strictly surgical and the abdominal route should be selected as the only rational approach to the cyst, although in the case of very small cysts some operators select the perineal route.

Nature of Amaurosis from Quinine Synthetics.

Ocular troubles from quinine have never been regarded seriously in ordinary medical practice, and doubtless not a few practitioners are unaware of their existence, despite the large literature of quinine amaurosis. It is otherwise with the quinine-copper synthetic known as ethylhydrocupreine. When the latter is given to pneumonia patients serious eye troubles are looked upon as a frequent and unpleasant complication. Many ophthalmologists have reported cases of this accident. In an article in the *Correspondenz-Blatt fuer Schweizer Aerzte* for November 16, Ujiie, pathological anatomist in the University of Basle, was fortunate enough to obtain an autopsy specimen of the eye. The patient was a ten-year-old girl with pneumococcus peritonitis, who was operated upon in vain. Death occurred from lung complication, with full amaurosis. A complete histological study was made with controls in the shape of eyes from pneumonic patients who had been treated with this drug without the supervention of eye troubles. The retina was the seat of edema and vacuole formation, with swelling and beginning degeneration of the nerve fibers and medullary sheaths in the opticus. The technique of the author was defective in one respect—he did not use the Marchi method; but Uhthoff's experience, in which this method was employed, gave the same finds. The conclusion is that in certain patients receiving ethylhydrocupreine in quite large doses the retina and optic nerve may be structurally damaged. Recovery or permanent injury may result from these changes.

Yersin's Bacillus and Influenza.

That carelessness on the part of even the most estimable bacteriologists may be responsible for erroneous and dangerous mental states on the part of both profession and public, well appears from an editorial in *El Siglo Medico* for November 2. One of the most distinguished bacteriologists in Spain in the course of a report of his finds in a study of the bacterial flora of influenza chanced to mention incidentally the presence in some specimens of a bacillus which presented certain morphological analogies with the bacillus of Yersin, otherwise of pneumonic plague. Such statements are common among bacteriologists' reports, and the mere fact of similarity never connotes identity. But this casual mention started a panic of such extent and intensity that Ramon y Cajal, at present chief of Alfonzo XIII Institute, was summoned to investigate and report on the nature of the germ in question. The latter, after preliminary studies, was pronounced to be something other than Yersin's bacillus. Cultures submitted by Dr. Maldonado were not cultures of the latter. The unknown organism did not range itself among those which produce a hemorrhagic sepsis or pasteurellosis and hence could not be regarded as a congener of the Yersin type. Finally, to end the matter once for all, it was proved to be a saprophyte of no pathogenic power. These facts were quite sufficient to close the incident, but the occurrence of the panic itself shows the weakness of the human mind in being made so jumpy by the unknown.

News of the Week.

The Roades Prize of the American Laryngological Association, amounting to $200, is offered this year in general competition for the best thesis upon some subject directly connected with Laryngology or Rhinology. Papers must be in the hands of the Secretary, Dr. D. Bryson Delavan, 40 East 41st Street, N. Y. City, prior to June 1st.

A Dinner in Honor of Dr. Caroline M. Purnell of Philadelphia will be given Saturday evening, March 8, 1919, at the Hotel McAlpin, New York City, by the American Women's Hospitals, whose commissioner in France she has been for the past five months. The American Women's Hospitals, besides its own hospitals in France, at Luzancy and La Ferté-Milon, which are staffed entirely by women physicians and dentists from its own membership, has also had almost one hundred of its members doing medical and surgical work under the American Red Cross in France, Italy, Serbia, and Palestine, and is now supplying medical women for the American Committee for Relief in the near East, six physicians having recently sailed to take charge of hospitals in Turkey and Asia Minor.

X-Ray Class for Women.—An *x*-ray school for women has been opened at Hunter College, New York City. The course will last from two to three months, and consists of dark-room technique, regulation of *x*-ray tubes, principles of machinery, placing of patients for various roentgenographs, making the exposure, etc. This is the first college to give systematic training in the technique of radiography.

Second Epidemic of Influenza at Sing Sing.—A new epidemic of influenza has appeared among the prisoners of Sing Sing Prison. The twenty-five prisoners who are ill with the disease have been isolated. During the former epidemic there were 90 cases of influenza in the prison, but, though several of these developed pneumonia, no cases resulted fatally.

Typhus Epidemic Rages in Moscow.—The State Department at Washington has received information that a party of French, British, Belgian, Italian, and American relief workers returning from Moscow to Stockholm, report that a frightful epidemic of typhus is raging in Moscow. There are said to be a thousand new cases of typhus in Moscow weekly, and the hospitals are overcrowded and unable to care for the patients.

Influenza Still Prevalent in Paris.—A report from Paris, under date of February 18, states that there is a marked increase in the number of cases of influenza reported for that week. The number of deaths from the disease for the three weeks ended on February 18 was 284,370, and 550, respectively.

Joint Influenza Committee.—The Department of Commerce, Bureau of the Census, Washington, D. C., announces that a Joint Influenza Committee has just been created to study the epidemic and to make comparable, so far as possible, the influenza data gathered by the Government departments. The members of this committee as designated by the Surgeon General of the Army, the Surgeon General of the Navy, the Surgeon General of the Public Health Service, and the Director of the Census are: Dr. William H. Davis, chairman, and Mr. C. S. Sloane, representing the Bureau of the Census; Dr. Wade H. Frost and Mr. Edgar Sydenstricker, of the Public Health Service; Colonel D. C. Howard, Colonel F. F. Russell, and Lieutenant-Colonel A. G. Love, United States Army; Lieutenant-Commander J. R. Phelps and Surgeon Carroll Fox, United States Navy.

London Physicians Form a Business Union.—A despatch to the New York *Sun* states that, in view of the impending establishment of the Ministry of Health and its consequent effect on the medical profession, a meeting of some London physicians, both men and women was held on February 23 and by a vote of 207 to 30 adopted a resolution favoring the immediate organization of the profession on a trade union basis.

Opposed to Prohibition.—At a meeting of the Medical Society of the County of New York, held on Monday evening of this week, a resolution was adopted by a large majority condemning the hasty ratification by the State Legislature of the constitutional amendment establishing prohibition.

Red Cross Unit for Poland.—The first contingent of the American Red Cross Commission for Poland left Paris on February 20. A second group followed two days later. The commission, of which Dr. Walter C. Bailey of Boston is head, consists of fifty members coming from all parts of the United States. The typhus epidemic is said to be spreading to all parts of Poland and cholera, smallpox, and trachoma are also very prevalent. A recent message to Paris, setting forth the unhappy condition of Poland, urges the immediate dispatch of medical supplies. These are being rushed from France and from the Red Cross warehouses at Danzig, Copenhagen, and Berne.

Red Cross Starts International Public Health Movement.—At a dinner in Paris, on February 21, delegates to the Peace Conference listened to an address by H. P. Davison of the American Red Cross in which he outlined the international plans for world welfare work. He stated that, impelled by the unparalleled suffering throughout the world, immediately after the armistice was signed representatives of the Red Cross societies of the different nations came together for the purpose of finding a way of coordinating the efforts of all Red Cross organizations throughout the world in the interest of mankind. The aim of the present program would be the establishment at Geneva of a bureau which would devote itself, not to the actual study of human diseases, but to the coordination of the result of such studies. Their first efforts would be to cover the subjects of public health and sanitation, tuberculosis, nursing, child welfare, and malaria, and certain other infectious diseases. It is believed that the result of this program will be to awaken the peoples of every country of the world to a sense of their obligation to their fellowmen, and that there will follow naturally in each country an awakening to the needs in that country and a determination to meet them as far as possible. A second result would be that light would be thrown on the darkest corner of the earth and would give to all the world the full benefit of scientific study and experience in the prevention and cure of

disease. In the third place it would make possible the immediate cooperation of the various organizations to render aid when necessary in the case of a great disaster.

Conference on Child Welfare.—The third annual conference of the New York State Association of Child Welfare Boards was held in New York City on February 19, 20 and 21. The Acting Mayor assured the delegates that the city officials would consider any program which the members of the boards agreed upon as promising the best results in child welfare work. Health Commissioner Copeland advocated Government control of milk and deplored the fact that a large proportion of the hospital beds of the city were in private institutions. Assemblyman Martin G. McCue gave his assurance that as a member of the Legislature he would advance legislation to make the work of the boards more effective. One aim of the boards at the present time is to secure further legislation providing for the maintenance of widowed mothers with young children, so that these mothers can remain in the home and protect their children.

Ohio State Medical Association.—The seventy-second annual meeting of this association is to be held in Columbus, on Tuesday, Wednesday and Thursday, May 6, 7, and 8. The forthcoming convention is expected to be the largest in point of attendance and interest in the history of the Ohio State Association. Among the interesting features which are being planed in connection with the exhibition will be the scientific exhibits by the State Department of Health, the Ohio Board of Administration, the Ohio School for the Blind, and the National Society for the Control of Cancer.

Gift for Johns Hopkins University.—At the commemoration day exercises of Johns Hopkins University, February 22, Dr. William H. Welch, who presided, announced that a sum of approximately $400,000 had been given for the erection of a building at the Johns Hopkins Hospital to serve as a woman's clinic. The gift is an anonymous one.

Public Health Service Starts Campaign.—Surgeon General Rupert Blue announced that a nationwide drive has been started for an increased number of public health nurses to assist in the prosecution of an after-the-war health campaign, which was begun on February 23, Public Health Sunday. For the first time in its history the Public Health Service, during the war, organized a division of public health nursing. The work which these nurses performed was of inestimable value in keeping down sickness in the extra cantonment zones during the war and in lowering the rate of venereal diseases in the army. The intention is now to continue the general plan of the work conducted by the Public Health Service and also the special fight against venereal diseases. Surgeon General Blue, in his announcement of the plans for a nationwide health campaign, appeals to the women of the country to support the public health nurse, to encourage young women to take up the profession of public health nurse, and to insist that hospitals provide training for nurses in public health service.

The American Board of Ophthalmic Examinations will hold its next examinations at the Wills Eye Hospital, Philadelphia, June 6 and 7, 1919. The coming examination will be the fifth to be conducted by the Board, which is composed of members of representatives of the American Ophthalmological Society, the Section on Ophthalmology of the American Medical Association, and the Academy of Ophthalmology and Oto-Laryngology. By arrangement with the American College of Surgeons, the Board has become the Ophthalmic Credentials Committee of the College, and conducts the ophthalmic examination of the ophthalmic candidates for Fellowship in the college. Details with reference to the examination may be had upon request from the Secretary, Dr. William E. Wilder, 122 South Michigan Avenue, Chicago, Ill. The Board is doing a valuable work in trying to raise the standard of ophthalmology in this country.

Vacancies for Physicians.—The New York State Civil Service Commission announces that examinations will be held on March 19, 1919, to fill the following positions: Consultant in Venereal Diseases, Department of Health, for men between the ages of 35 and 55 years. Applicants for this position must have special training and experience in the diagnosis of venereal diseases. The position carries a salary of $3,000 a year. Assistant Physician, Regular or Homeopathic. This examination is intended to provide eligibles for the position of assistant physician in the State Hospitals and for other positions of a similar nature in State and County institutions. The examination is open to men or women who have had six months' experience on the resident medical staff of a general hospital or as medical interne in a State Hospital or institution, or have been engaged for one year in the practice of medicine. The salary is $1,200 with increase.

An examination is also announced for the position of Assistant Bacteriologist, Quarantine Laboratory, Department of the Health Office of the Port of New York, for men only. This position carries a salary of $1,200. An examination for Dietitian, Hoffman Island Quarantine Station, lower New York Bay, Health Officer's Department is open to men and women, and carries a salary of $900 and maintenance. In writing for application the candidates should specify the particular position for which they desire to be examined.

Vacancies for Nurses in New York Health Department.—There are seventy-four vacancies for nurses in the New York Health Department at a salary of $960 a year. Application for permission to take the examination for these places must be in the hands of the Municipal Civil Service Commission before March 13.

Pan-American Child Welfare Congress.—The United States has been invited through the Uruguayan legation to send delegates to the Second Pan-American Congress for the Welfare of the Child to be held at Montevideo. The congress will meet May 18 to 25, the session having been postponed several times because of the war.

The Massachusetts Medical Society has found it necessary to change the date previously set for its next annual meeting. It announces that the

next annual meeting will be held on June 3 and 4, 1919.

Indians Ravaged by Influenza.—Reports from Cross Lake, eighty miles north of Winnipeg, indicates that influenza has almost wiped out the Indian population in that district. According to the report there are no physicians near to give aid.

The Southern Medical Association, the annual meeting of which was omitted in 1918 because of the influenza, will hold its next session at Asheville, N. C., November 10-13, 1919.

Dr. C. W. Goddard of Holland has been appointed Health Officer of the State of Texas.

Honorary Degrees.—At the annual celebration of Washington's Birthday the University of Pennsylvania conferred the degree of Doctor of Laws on Dr. William Williams Keen of Philadelphia and on Dr. Frederick Peterson of New York City.

Wills Eye Hospital, Philadelphia.—Dr. William Campbell Posey has resigned as attending surgeon and has been elected consulting surgeon. Dr. Thomas E. Conrad has been elected acting attending surgeon.

A Dearth of Vital Statistics.—Marysville, Pa., one of the smallest boroughs in the United States, having less than 100 inhabitants, has made a new vital statistics record, in that it did not report a death during the year 1918. It also made a new record in that but a single birth occurred during the year. This is one of the very few districts in the country that did not report a death during the past year.

Medical Society Elections.—The WARE COUNTY (GA.) MEDICAL SOCIETY, at its annual meeting, held Feruary 10, elected the following officers for the ensuing year: *President*, Dr. G. N. MacDonald; *Vice-President*, Dr. J. H. Latimer; *Secretary-Treasurer*, Dr. W. F. Reavis.

The PORTSMOUTH (N. H.) MEDICAL SOCIETY, at its annual meeting, held February 4, elected the following officers for the ensuing year: *President*, Dr. M. A. Higgins; *Secretary*, Dr. C. W. Hannaford; *Treasurer*, Dr. E. B. Eastman.

The WESTERLY (R. I.) PHYSICIANS' ASSOCIATION, at its annual meeting, held February 7, elected the following officers for the ensuing year: *President*, Dr. Henry L. Johnson; *Vice-President*, Dr. J. DeVere Barber; *Secretary*, William A. Hillard; *Treasurer*, Dr. John Champlin; *Censor for three years*, Dr. Frank I. Payne.

Obituary Notes.—Dr. MARY WALKER, a practising physician, and an army surgeon, died at her home in Oswego, on February 21, aged 87 years. She volunteered her services at the beginning of the Civil War, and served four years in the field, receiving the Congressional Medal of Honor. She was an ardent advocate of feminine dress reforms, and was the only woman allowed to appear in male attire by act of Congress. She was also a pioneer woman suffragist, being active in the support of various woman's rights measures. In addition to her political and dress reform activities she continued to practise medicine until within two years of the time of her death.

Dr. HENRY H. BOBB of East Greenville, Pa., died of heart disease on February 10, at the home of his son-in-law, in Philadelphia, Dr. J. Parsons Schaffer, at the age of 72 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1868.

Dr. WM. P. PAINTER died at Darby, Pa., on February 14, at the age of 77 years. He was graduated from Jefferson Medical College in the class of 1875. He was vice-president of the First National Bank of Darby.

Dr. THOMAS R. STRASSER died at Reading, Pa., on February 15, at the age of 73 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1867. He was at one time physician to the Lehigh County Hospital.

Dr. EDWIN M. HERBST died at Oley, Pa.,, on February 17, at the age of 62 years. He was graduated from Jefferson Medical College in the class of 1878. He served at one time as Pennsylvania State Senator, was physician to the port of Philadelphia from 1891 to 1893, and United States pension examiner at Reading from 1893 to 1898.

Dr. ERLO ELSTEN KENNEDY, a graduate of Baltimore Medical College, in 1905, formerly of Basalt, Col., died of pneumonia at his home in Denver on February 4, aged 38 years. Dr. Kennedy was at one time Mayor of Basalt, later representative of Eagle County at the Nineteenth General Assembly, and at the time of his death secretary of the State Board of Health.

Dr. JONAS M. O. TUFTY, a graduate of the University of Norway, in 1885, died at his home in Duluth on February 3, aged 61 years.

Dr. A. LOWRY IVINS, a graduate of the New York Homeopathic Medical College, in 1911, for a time in charge of the hospital of the Braden Copper Company at Santiago, Chile, died at his home in Sayville, L. I., on February 22, of pneumonia following influenza, aged 32 years.

Dr. ALFRED M. GOODALE, a recent graduate of Harvard Medical School, and prominent in the athletics of that institution, attached to the staff of the Boston City Hospital, died of pneumonia on February 21.

Obituary.

JAMES TYSON, M.D., LL.D.,

PHILADELPHIA.

DR. JAMES TYSON, who died on Friday of last week, at the age of 77 years, was born in Philadelphia and received his premedical education at Haverford College. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. He served as resident physician in the Pennsylvania Hospital in 1863-4 and as Acting Assistant Surgeon in the United States Army from 1863 to 1865. In 1868 he became lecturer on microscopy in the University of Pennsylvania, in 1870 lecturer on urinary chemistry, in 1874 lecturer on pathological histology, in 1876 professor of general pathology and morbid anatomy, in 1889 professor of clinical medicine, in 1899 professor of medicine, and in 1910 emeritus professor of medicine. He was secretary of the Faculty of Medicine from 1877 to 1888 and Dean from 1888 to 1892. He served also as physician to the University Hospital, a member of the Board of Managers from 1874 to 1877

and again from 1891 to 1910. In 1866 he became microscopist to the Philadelphia Hospital, in 1870 pathologist, and in 1872 visiting physician. He was one of the incorporators of the Rush Hospital for Consumptives and one of the trustees. He was consulting physician to the Kensington Hospital for Women and to St. Mary's Hospital. He was a fellow of the College of Physicians of Philadelphia and at one time its president, a member of the Philadelphia County Medical Society and at one time its president, a member of the Medical Society of the State of Pennsylvania and at one time its president, a member of the American Medical Association, a member of the Pathological Society of Philadelphia and at one time its president, an original member of the Obstetrical Society of Philadelphia, one of the founders of the Association of American Physicians, a member of the American Climatological Association and of the American Philosophical Society. He had served as president of the Pennsylvania Society for the Prevention of Tuberculosis. He was the author of numerous text books and treatises on medical subjects and a frequent contributer to periodical medical literature.

JOHN ALFRED BODINE, M.D., F.A.C.S.,

NEW YORK.

Dr. John Alfred Bodine, of this city, who died suddenly of angina pectoris on Monday of this week, was for nearly twenty-five years closely connected with the New York Polyclinic Medical School. He was born in Kentucky in 1865 and was descended from a line of medical men, his father and grandfather having been well known surgeons in their day. He was graduated in medicine from the University of Louisville in 1893 and soon thereafter began practice in New York City. He was a member of the New York Academy of Medicine, of the Medical Societies of the County and State of New York, of the American Medical Association. He was visiting surgeon to the New York Polyclinic Medical School and Hospital, and consulting surgeon to St. John's and the Long Island College Hospitals, and to the Northwestern and the Northern Dispensaries.

Correspondence.

THE HEALTH INSURANCE BILL.

To the Editor of the Medical Record:

Sir:—In reply to the letter sent to the president of the Medical Society of the State of New York, and kindly published in the Medical Record, I take pleasure in stating that I have just received a letter from the president of the State society in which he says: "I am sending a letter to each president of the county societies calling his attention to the health insurance bill, and urging a special meeting be called to discuss the question." Word received from Erie County is to the effect that the society not only condemned the health insurance bill but that a number of members signed an agreement not to work under it if passed.

It remains for every physician to let his Assemblyman and Senator know at once his attitude on this form of legislation for the socialization of medicine.

John P. Davin, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, January 29, 1919.

The Annual Birth Rate and the Toll of Youth.—From several official sources as well as from the authoritative statements of private persons in a position to know, it is fairly clear that one result of the war has been that the age-constitution of many nations has seriously altered, even though the actual numbers of the populations have not varied much—the total population may as in the case of Great Britain have actually increased. It had been observed as a matter of fact before the war that the extension of the age limit and therefore of age expectation was marked in many countries while in Great Britain the birthday of a centenarian was so frequently reported as to pass unnoticed and the obituary columns of the great daily papers were studded with announcements of the deaths of persons between the ages of 85 and 95. For obvious reasons the destructive hand of war has been particularly heavy on the young. Young men have perished literally by the million; an undue number of young women have succumbed to the altered conditions of life and the severe strain of war work—the size of this figure is however much in dispute—and lastly the infant and child death rates have enormously increased. One other factor making the proportion of births, and therefore of young lives, abnormally small must also be alluded to. It is undoubted that practices in prevention of conception, formery confined to the wealthier and more luxurious classes, have now become common in all grades of society, and the small size of all families had become notorious several years before William of Germany willed a war. The whole position is one that requires great attention previous to the institution of any series of remedies, and it is to vital statistics that we must all look for guidance in future policy. For that reason the recent announcement in *The Lancet* that the Registrar General, Dr. T. H. C. Stevenson, has proposed the inauguration of a "single master register" for the United Kingdom is of great significance. There has been no census in this country since 1911, and a proper enumeration of our population is urgently required. If, as would naturally be expected, the Ministry of Health, when founded, decides to embark with determination upon a large and inclusive scheme for the improvement of the national health it is on medical statistics that reliance must be placed, and just such a register as Dr. Stevenson has adumbrated will then have to be formed as a basis of all operation as well as a test of all proceedings. The register, to be truly "master," should include every man, woman and child in the country, and should give particulars of name, address, sex, age and occupation, the date of birth, and other information concerning marriage and family history should also be provided; many of these details finding place in special registers forming supplements to a coordinated system, and subject to a central index. The Commission for the Reconstruction of the National Birth Rate has now resolved that there is immediate need for such a "single master register," and the appointment of two medical men, Dr. Addison and Sir Auckland Geddes, as members of the Government upon whom the constructive policy of the Ministry of Health

will devolve, is a good earnest of prompt activity. There are so many charitable, benevolent, and semi-medical agencies in existence working on more or less parallel lines, and having as at least one of their main objects to maintain a proper birth-rate and minimize the opposing forces which lead to abnormal death-rate among the young, that there is some risk of energy being wasted through overlapping or misdirection. Legislation is sure to be set in hand at once to promote proper housing of the poorer classes and so to provide the environment in which the birth-rate should have proper chances. There are many voluntary bodies working at different objects of this reform. The National Council for Combating Venereal Diseases, by the eradication of the specific poisons as well as by the prevention of their spread, aims both at increasing the number of healthy children born and at giving good chances to those who are cruelly born with a taint. Further, many associations founded in behalf of maternity and child welfare are playing a useful part. Crêches are being established in connection with such welfare work in or near factories where mothers are employed, thus recognizing that, though the best place for the mother may be in her home, social conditions may compel her to be working outside. All this work requires to be coordinated and should find its logical center in the new Ministry of Health, the possible range of whose labors is unlimited. And a "master" register would serve the purposes of all existing activities, and would indicate with all the force of accurate figures both the places where evil was most rampant and the units where work was being duplicated wastefully.

The Value of Moral Education.—In connection with certain statements respecting the prevalence of venereal disease in the navy in the early days of the war, the Reverend Bevill Close, who was chaplain from September, 1914, to April, 1915, with a large Royal Naval Division quartered at the Crystal Palace, London, has made a public pronouncement upon the value of moral education in such circumstances. Upwards of 12,000 men passed through the Crystal Palace depôt between the dates of his holding office, but as each new draft arrived the highest moral ideal was placed before them by the chaplain, whose teaching was reinforced by both medical and executive officers. Leave was granted to the men every evening and only forty venereal cases had to be recorded!

The Housing Problem.—For a long time the housing of the industrial classes, that of the agricultural laborer no less than that of the urban worker, has been discussed as a matter that must be immediately dealt with by the Government upon the cessation of the pressing business of the war, and here again the Ministry of Health will have to assume vast responsibility. Doctors and philanthropists, clergymen and statisticians, employers of labor of all kinds, and the employees of every class and grade have discussed the matter at by and large, and now the time is clearly approaching when something is about to be done. It is, for example, an open secret that Dr. Christopher Addison holds his portfolio at the Local Government Board in response to his own direct wish to deal with housing, and it is now understood that a Government scheme is in existence to meet the necessary cost of a huge piece of domestic reform. The Government has under consideration the payment of no less than 75 per cent. of the loss incurred by building new houses for the industrial classes, by acquisition and alteration of existing buildings, by the purchase of sites, and so on, it being recognized that there must be a loss because no economic existing conditions could possibly allow, save in exceptional circumstances, the payment of any rent large enough to constitute profitable interest on the capital involved. The other 25 per cent. of any loss incurred will, it is suggested, be produced by a rate amounting to one penny in the pound, but it is clear that many urban communities could afford more than this rate, while some rural districts will be hard put to raise the money. From the medical point of view it is essential that when the building schemes begin, no cheeseparing policy should be pursued, though no money should be spent on what may be called architectural frills. Soil, site, aspect, water supply, and convenience of transit and transport must all be considered without much eye to the total cost, but unnecessary gables, sham mullions, foolish railings, and all the delights of the inferior builder must be suppressed. It is possible that the lesson of the sanatoriums for tuberculosis will remain in the minds of those who have the spending of money on the housing schemes. Medical men will never forget the profuseness with which money was poured out to place these institutions where they do not appear to serve local wants, and to construct them at needless cost with a vast responsibility for repairs incumbent upon them. The note of the new houses must be simplicity. The position was well summed up at the recent presidential address of the Royal Anthropological Institute. The president, Sir C. Hercules Read, the keeper of the Mediaeval Antiquities in the British Museum, speaking of the housing of the community in the future, and declaring that in this direction we must look for the greatest amelioration in the physical condition of the people, said that three qualities were wanted in the ideal residence, in this order: (1) Healthiness, (2) convenience, and (3) beauty. Usually these things were put in the reverse order, he said, and the final result was that the cost was so high as to make it impossible for anyone but a generous Government to build a workman's cottage. The Office of Works, although its functions ranged from the erection of a new Embassy at Peking to the mowing of the lawns at the British Museum, had had no man whose function it was to provide for the erection of suitable houses, and he supposed it must now be left to a Ministry of Health.

The Special Clinical Meeting of the British Medical Association.—As I announced recently, this meeting, in substitution of a general annual meeting, will be held in April next. Mr. Cuthbert Wallace, surgeon to St. Thomas's Hospital, Mr. S. Maynard Smith, surgeon to St. Mary's Hospital, and Dr. Gordon Holmes, physician to Charing Cross and the Royal Ophthalmic Hospitals, have accepted jointly the general secretaryship, and Mr. C. H. S. Frankau, surgeon to St. George's Hospital, and Colonel des Crespigny and Major Ellis, of the Australian and Canadian Army Medical Staffs, respectively, will act as the organizing secretaries of the three sections of surgery, medicine, and pathology.

Death of Sir James Sawyer.—Sir James Sawyer, whose death has just been announced, was consulting physician to the Queen's Hospital, Birmingham, and was well known in the political as well as the medical world.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, January 16, 1919.

Horrible Fate of the Children of Lille.—No one can read without pity, nor, to use President Wilson's words, "without horror and a burning heart," the petition of the mothers of Lille imploring the French government to demand of Germany the instant return of their children whom the Huns have carried off into captivity. The list of those taken from Lille alone comprises 4,068 names. Thirteen are children of fourteen years of age, 1,100 are fifteen, 1,447 are sixteen, and 1,499 are seventeen. We beg "the Government of the Republic," says the petition, "to summon the German government to restore to their mothers the children who have been carried off and are retained in contempt of the law of nations. We are tortured by the thought that they are being dragged along with the barbarous hordes fleeing in disorder, that they are at the mercy of heartless and pitiless men, and that, enfeebled by four years of unheard-of privations, they are exposed to all the dangers and sufferings of a routed army."

At the present moment, when Germany to escape the punishment of her crimes is pretending to reform her governmental system, it is well that this pathetically terrible indictment be given the fullest publicity. The system certainly was monstrous and in need of reform. But what about the people? The system was the product of the nation; it faithfully reflected the nature of the most abject savages that ever disgraced the human race, arrogant and merciless in victory, groveling and treacherous in defeat. The efforts that have been and are being made to distinguish between the Huns and their masters, to whitewash the people and incriminate only the "ruling caste," fill one with pity for the naiveté or contempt for the duplicity of those making the efforts. This war is the war of the German people. It is repudiated by the people now only because the Germans' treacherous and bloody aggression on civilization has failed. Did the German people protest in 1914? Gloating over the prospect of booty, of war indemnities, trade privileges and territorial acquisitions, the German people, like one man, hailed with joy the opening of the long promised and impatiently awaited "fresh and frolicsome war," and rushed to participate in it and the pillage.

Four times in a century the German hordes have delibrately drenched Europe with blood. Four times in a century they have poured into France, murdering, burning, plundering; the entire race, officer and private, shopkeeper and laborer, professor and peasant, welded into a solid block by lust and envy and avarice. Read the indignant protestation sent by Lille scientists, Drs. Calmette, Parenty, Witz, and others, to the Academy of Science, and read at the meeting of that eminent body last Monday. Some purblind or callous pacifists urge that the people is not responsible for the crimes of its leaders. But, protest the signers of the protestation, those who have witnessed, as we have, the readiness and zeal displayed by all the troops, young and old, in the execution of their orders, must feel convinced of their complicity.

Proof of that, if further proof were needed, would be found in the hideous *razzia* which has called forth the pitiful petition from Lille, a petition signed by 5,000 mothers robbed of their children. For the nation guilty of such bestiality can any punishment be too severe? Can any conditions to prevent further German barbarity be sufficiently rigorous? It is not the Kaiser and the "ruling caste" alone that must be shackled; it is the entire horde that must be rendered powerless for evil in the future. Any weakness in dealing with the enemy of mankind, the German people in its entirety, would be fatal. M. Clemenceau's powerful declaration is dictated by a spirit of strict justice and by a sense of duty to humanity: "The most terrible account has been opened between people and people. It shall be paid!"

The *Berliner Tageblatt* now demands an official investigation of the charges laid at the door of the German army and its chiefs. But nothing was said so long as the fortune of war seemed to be favoring the criminal nation; no one, from prince to peasant, condemned the nameless horrors committed in France and Belgium—the ruining of entire provinces, the razing of towns, the driving forth of hapless citizens, the torture and maltreatment of women and girls, the deliberate destruction of hospitals, and murder of wounded, the creating of awful deserts where once were fertile fields and orchards. For all this hideous work of bestial ferocity the German nation has a direct and crushing responsibility.

Measures to Curb the Influenza Epidemic.—Serious steps are now about to be taken by the Paris authorities to cope with the insidious malady sometimes described as "grippe," influenza, or "Spanish flu," but which in innumerable cases develops all the symptoms and results of bronchopneumonia, congestion of the lungs, and other diseases on whose orthodox medical classification no doubt whatever can be cast. It had been intimated in some quarters that the epidemic is already distinctly on the decline in the city of Paris, if not throughout France, but the suggestion is not borne out by figures which the *Temps* publishes and emphasizes. When it is remembered that the scientific and medical staff of the *Temps* includes some of the greatest authorities in Europe it will be understood that the *Temps* analysis of the situation should be accepted even by those professionally disposed to be censorious of "newspaper reports." The *Temps* mentions that the deaths in Paris from the vague disease and its complications during the forty-third statistical week of the year were the highest since the outreak of the epidemic. The death rate rose on October 27, October 28, and October 29, and on the last-mentioned date 230 deaths were recorded. The 2,566 deaths of the forty-third statistical week included 1,263 attributed to "grippe." These are tabulated as follows:

Males	Females	Age
16	10	0 to 2 years
12	36	2 to 9 years
68	98	10 to 19 years
212	493	20 to 39 years

Males	Females	Age
100	122	40 to 59 years
38	58	60 and over
446	817	

From this table it is clear that adults between 20 and 50 years of age are most liable to the fatal forms of the disease, and that, proportionately, women pay the highest death tribute. While many provincial cities have taken active measures against the epidemic, there has been considerable laxity in the capital. At Montceau-les-Mines the mayor has had all the churches, theaters, and cinema halls closed, and has installed a special influenza hospital outside the industrial district. At the Creusot the necessity of supplying milk for the sufferers has led to the suppression of milk cards for healthy children over 18 months of age. The *Temps* urges that the numerous precautionary measures adopted in the provinces should be at least extended to Paris, and that something should be done to diminish the present chaos regarding the difficulty of obtaining the remedies prescribed by physicians, milk, and nearly all the requisites for invalids in Paris. Meanwhile, Parisians have been notified that the Minister of Food Supplies has "released" 50,000 liters of rum to enable influenza patients to be supplied with hot, stimulating drinks when prescribed by their medical attendants. The "release" was formally made two or three days ago, according to the Paris press, but has not yet reached the chemists' shops through which it will be dispensed.

The United States Army Ambulance Service attached to the French Army will continue work with the French divisions which are marching into Germany. The American sections will be disbanded only when the French divisions to which they are attached are demobilized. We now have 82 sections composed of 45 men each, nearly 3,700 men of this ambulance service serving with the French, and while they are all glad that the war is won, and want to go home as soon as possible, they realize that there is still more work to be done, and they are interested to continue their share until the end. There will be no change whatever in the status of these American ambulance drivers with the French divisions. Although their duty consisted in transporting the wounded from the battlefields, and that particular work no longer exists, the divisions of which they form a part will not demobilize. About ten sections have been detached from divisions which are not going into Germany and are employed in civilian work in the Lille area and also around Rheims. The U. S. A. A. S. has handled about 70 per cent. of the French wounded. These figures are not as yet official, but it is reasonably certain that they are not exaggerated.

Returning Prisoners.—Hundreds of prisoners returning from Germany are now arriving daily in Nancy, Luneville and other towns near the frontier. Most of them are British and Canadians, but there are also many French and a few Americans. The Y. M. C. A. in Nancy and the Foyer du Soldat, the Y. M. C. A. in Luneville, and other towns in Lorraine, are working with the Red Cross and other relief organizations to take care of the men as they arrive. The famous natural hot-water baths at Nancy, which are under the jurisdiction of the Y. M. C. A., are being diverted to the use of the ex-prisoners, and the Red Triangle is providing baths for a thousand men each day. All hotels at Nancy are crowded and private houses are being opened to the men until they can recuperate. British officers are also on the job. They are bringing in truckloads of old uniforms and also many new uniforms of the British Royal Flying Corps, in which the ex-prisoners are blossoming out from the baths.

6. Tonic Muscle Spasm; Its Significance as a Clinical Phenomenon.—J. Madison Taylor points out that the element, or phenomenon, of spasm is an exceedingly common denominator, affording the key to diagnosis and to relief, or even at times to cure, of manifold distresses and disorders, among which may be mentioned the group of "colics," intestinal, uterine, cholecystitic, nephritic, cystitic, pyloric, etc.; disturbances of function nonsensory, such as suppression of urine, of defecation, or respiration, etc.; and vertiginous states, disorders of special sense of eye, of ear, or throat, and various forms of backache. Familiarity with norms is, of course, essential in diagnostic exploration. Anomalies in resistance will be revealed, the localized spasms or contractures in muscles and bundles bearing direct relationship to irritated centers, and these again to sources of irritation on the periphery. Under certain conditions tenderness on firm pressure will be found. The source of irritation can be thus inferred to lie in a particular area and to be more pronounced on one or other side, indicating that fuller explorations are required in the suspected area. It is especially interesting to know that judicious, gentle manipulation brings about marked mitigation of spasm and tenderness with relief to the overwrought center and, efferently, to the lesion or disordered area. The action is a blend of interactions, one involving spinal centers and sympathetic centers—and explainable through the autonomic nervous system. The diagnostic spasm and tenderness is most pronounced in the paravertebral structures close to the backbone. Until this spasmodic state is relieved much suffering and often serious peril continues. In any exigency, when the phenomenon of spasm can be reasonably inferred, it is the part of wisdom and economy to focus attention upon its relief, which may also readily become a cure of remoter conditions. Excess, unrelieved spasm stress leads to shock, which may prove actually fatal through strain.

1. Typhoid Fever Occurring After Prophylactic Inoculation.—Claude P. Brown, Francis W. Palfrey, and Leonard Hart report a number of cases of typhoid fever which began to appear about the end of June, 1918, among troops stationed at Camp Greene, N. C. Of the cases reported twelve had previously received the full dosage of antityphoid vaccine, two recruits had each received two doses of vaccine, two had received a single dose each, and two had not been inoculated. A mild epidemic of typhoid occurred concurrently in Charlotte, the nearest city to the camp, and infection was thought by the health authorities to be fly-borne. As this mode of infection was not considered probable in the camp, careful investigations were made in regard to the milk, water, and ice used, but no particular information was elicited. Cultural examinations were made of the blood, urine, and feces of the eighteen cases reported; the blood was positive in thirteen cases, or 72.2 per cent.; the urine in the same number of cases, and the feces in nine, or 50 per cent. Cross agglutination tests showed wide variation, both as regards individual strains and the preparation of the agglutinating fluid by different methods, thus demonstrating the desirability of using standard agglutinating fluid for Widal tests. The results of these tests also strongly suggest that the same method should be used in checking the agglutination of patients' serum with the homologous strain. The authors conclude from their observations on these cases that occasional cases occur in which the usual preventive inoculations against typhoid fever fail to protect against the disease, most probably on account of the ingestion of virulent organisms in massive doses. They suggest the following precautions as a means of prevention: (1) Care should be taken that cooks and food handlers are not changed and new ones put in their places without examination for carriers of *B. typhosus*. (2) Special inquiry should be made by the surgeon of all prospective cooks and food handlers with reference to their having had typhoid fever, and note of this made when specimens are submitted for examination. (3) Repeated examinations should be made of prospective food handlers whose history is suggestive of typhoid fever before the men are accepted for such work. (4) Clinical cases of typhoid fever should have intensive study made of both urine and feces.

4. Nasal Obstruction in Aviators.—Captain Douglas Guthrie points out the importance of good binocular vision and normal ears to the air pilot. We must remember that the ear is not only the organ of hearing, but also an accessory organ of equilibration. In addition to a sound heart and sound lungs, a stable nervous system, and a healthy "mentality," the aviator must possess good vision, on which he mainly depends, and a sense of equilibration. It is regrettable that the latter, which is so highly developed in birds and may be so accurately estimated in man by the Bàràny tests, has received so little attention. Free nasal respiration is an important asset to the flying man. The author has had occasion to examine and operate on a number of officers suffering from nasal obstruction and, from his experience, summarizes as follows the baneful effects of such a condition in the aviator: (1) *Effect on the lungs.* It has been experimentally demonstrated by Mendel that the amount of air which the mouth breather inhales with each breath is less by one-fifth than the amount inhaled in normal nasal respiration. It follows, then, that if the subject be an aviator he will readily suffer from symptoms of "Oxygen-want." (2) *Effect of equilibration.* The Eustachian tubes, the function of which is to adjust the pressure of air within the middle ear to the changes produced by sound-waves, atmospheric pressure, etc., and which come into use so largely during flying, are impaired in their function if any nasal obstruction is present. During a rapid descent the tympanic membranes are driven inwards by atmospheric pressure, causing deafness and earache. Normally these symptoms disappear if the ears are "inflated" by swallowing or by movement of the jaw. But if the nasal passages are blocked so that air does not freely reach the Eustachian tubes the alteration of pressure within the middle ear cannot be compensated and the symptoms persist, perhaps with the addition of giddiness caused by altered labyrinthine tension, communicated from middle to inner ear through the round and oval windows. Under such circumstances the risk of a crash is naturally considerable. (3) *"Reflex" effects.* A third possible result of nasal obstruction is headache coming on in the air or after landing. This is in many cases due to a deflected nasal septum against the middle turbinal, the socalled reflex nasal headache. The commoner causes of nasal obstruction are adenoids, hypertrophic rhinitis, and septal deviations. In the majority of cases examined obstruction was due to deformity of the nasal septum, the patient usually giving a history of former injury at boxing or football. In some cases there was almost complete obtsruction of both nostrils; in others, symptoms were nil. Aggravated cases of septal deformity require treatment naturally, but the wisdom of operating on minor degrees of deviation in cadets is questionable, since absolute symmetry is rare. It should be noted, however, that a degree of nasal obstruction which would cause little trouble on the ground may be very troublesome in the air, for at heights over 7000 to 10,000 feet the mucous membrane of the nose becomes swollen and engorged and any existing obstruction is greatly aggravated. In the treatment of such cases, the main object, from a military point of view, is to render the patient fit as quickly as possible, and therefore local anesthesia is advisable. A method which answers well is to pack both nasal cavities half an hour before operation with 10 per cent. cocaine, and at the same time give a hypodermic of morphine and atropine. After-treatment consists in packing both sides with ribbon gauze wrung out in liquid paraffin, a dressing which adapts itself to the tissues and is easily removed on the following day. Treated in this way, septum cases need remain in hospital for only a few days.

5. Post-Influenzal Hemoptysis.—Horace Wilson draws attention to those cases in which hemoptysis occurs with influenza and which may be mistaken for pulmonary tuberculosis. As a rule the hemoptysis commences towards the end of the illness, when there is a light cough, an increasing weight, and no great tendency to wasting. The sputum shows a bright red staining, and not the typical rusty tint of acute pneumonia. Pneumococci are the predominant organisms and tubercle bacilli are absent. The characteristic physical signs are generally marked by their bilateral posterior distribution in the suprascapular areas, where breath sounds are faint and moist granular adventitious sounds are abundant, with no bronchial breathing and some bilateral impairment of the percussion note. The corresponding areas in front show little or no change, excepting some lack of resonance on percussion. The mid-area of the lungs posteriorly is fairly clear, but the bases show congestive crepitation on both sides. The temperature for a time is irregular and fluctuating, but pulse is not so rapid as in a tuberculous case. There is subsidence

of symptoms in a few weeks, with increasing weight and improved general condition. If, therefore, with slight hemotypsis the physical signs are bilaterial and chiefly marked posteriorly, a hasty diagnosis of pulmonary tuberculosis should not be made but frequent examinations of the chest and sputum should be undertaken and the general progress of the case taken into consideration. Many such cases have proved to be pneumococcal and transient. As regards the physical signs the converse hold good, and monolateral anterior signs with hemoptysis point to early pulmonary tuberculosis, particularly with no regain in weight, rapid pulse, and night sweats.

2. Public Measures for the Prevention of Tuberculosis. Lieut.-Col. Nathan Raw, C. M. G.
3. An Investigation into the Incidence of Albuminuria and Casts in British Soldiers During Training, and the Relationship of This Condition to War Nephritis. Captain H. Maclean.
4. The Policy of the Ostrich. Colonel J. G. Adami.
5. Recent Experiments on the Life History of Ascaris Lumbricoides. Major F. H. Stewart.

1. Herpes Zoster: Its Cause with Varicella.—R. Cranston Low reports three cases of herpes zoster, each of which was followed by one or more cases of chicken-pox either in the same family or in the same hospital ward, after an interval of nineteen, thirteen, and two days respectively. These cases support similar observations made first by Bokay in 1892 and since then by a number of other observers. In all the recorded cases the chicken-pox eruption appeared in from eight to twenty-one days after contact with a case of herpes zoster. In one of the author's cases, two days interval only elapsed between the appearance of herpes zoster and chicken-pox but as both patients had been in hospital for some time, the infection was probably brought by visitors. The converse condition, that is chicken-pox followed by herpes zoster, has also been reported by several observers, but not so frequently. Further, cases have been recorded from time to time in which herpes zoster and a varicella-like eruption have occurred in the same individual. These facts would lead one to conclude that the two conditions are due to the same virus. The author would go further, and suggests that in herpes zoster the infection is probably local, through the nose, along the lymphatics, round the olfactory nerves, as has been shown to be the mode of infection with the virus of anterior poliomyelitis, which has many points of analogy with herpes zoster. Once the virus reaches the meninges and cerebrospinal fluid, it is easy for it to get to the ganglia on the sensory nerve trunks. In chicken-pox there is probably a blood infection with the virus. In cases in which the two conditions appear, the virus probably attacks the ganglia first and, four or five days later, gets into the general circulation. Microscopically, the vesicle in herpes zoster is similar to that seen in the early stages of varicella. The lesions in chicken-pox occur in groups, suggesting that a small branch of the peripheral nerve is the seat of a focus of infection. Moreover, many of the chicken-pox lesions show a vesicle with no inflammatory halo around it, as is seen in pemphigus and dermatitis herpetiformis, which are generally considered to be nerve lesions. These facts would seem to show that the eruption in varicella is primarily not due to the virus settling in the end capillaries of the skin but in the nerve endings or minute nerve twigs in the skin. No causal organism has yet been discovered in chicken-pox or herpes zoster. It is possible that the virus belongs to the group of filter-passing ultramicroscopic organisms mentioned by Flexner in his Huxley lecture as being the cause of poliomyelitis and vaccinia among other diseases. Since both chicken-pox and herpes zoster occur in epidemic form, if they have a common origin one would expect simultaneous epidemics to occur. The only instance on record is that reported by Heim as occurring in Budapest during April and May, 1912. As neither disease is notifiable, statistics are wanting. As regards immunity, an attack of chicken-pox usually conveys immunity for life. Similarly, an attack of herpes zoster is rarely followed by another; most of the recurrent attacks are attacks of peripheral neuritis due to pressure by a tumor on nerves. An attack of varicella does not necessarily protect the individual against herpes zoster. It is possible that an attack of herpes zoster may confer immunity to chicken-pox, but individuals who have herpes zoster in many cases are past the age when they are likely to have the former. Further knowledge is required on this point. In cases of herpes zoster which occur whilst arsenic is being taken, the question arises whether the arsenic produces an arsenical neuritis with the eruption in the distribution of the nerve, or whether the arsenic renders the nervous system more susceptible to infection with herpes zoster. The latter would seem to be the more probable explanation, because even although the patient continues to take the arsenic, the herpes zoster runs a normal course, heals up, and does not recur. Parkes Weber, moreover, reports an instance in which a patient was taking arsenic and developed herpes zoster with a generalized varicella-like eruption, and another patient from the same ward developed chicken-pox fifteen days later.

4. The Policy of the Ostrich.—Colonel J. G. Adami draws attention to the ravages of venereal disease in the British army both before and particularly during the war, and to the policy of the ostrich, as he aptly describes it, with which conditions have been met. Describing conditions as they existed in England in 1914, Colonel Adami refers particularly to those at Salisbury Plain upon the arrival of the first Canadian Contingent in the autumn of that year. He commends the work of the National Council for Combating Venereal Diseases though he deplores their tardiness in taking definite action, "so heavily did the dead hand of Mrs. Grundy press upon them." Colonel Adami makes an earnest plea for frankness and open speaking. Had the medical profession in the first place, the National Council, and the Government spoken out at the beginning of the war, conditions would have been very different today. Even now much might be accomplished were the National Council to influence the Government to publish a statement regarding the venereal disease situation in the army in successive years of the war in the different regions, and also obtain powers to make an investigation into the frequency of syphilis or venereal disease in general in selected areas or classes of the population. Let the situation be known and faced. America did not hesitate to speak out, even before the war. In 1912, the Surgeon-General at Washington published regulations directing all soldiers returning to camp to state whether they had exposed themselves to the possibility of venereal disease and detailing early preventive treatment. General Pershing, moreover, made it one of his army regulations that the venereal status of a unit should be taken into account in determining the promotion of the officer commanding. In the overseas forces of Canada all the methods instituted in the American army, with exception of court martial, are now employed, namely, education, warning, recreation, diversion, protection, isolation, prophylaxis, and penalties. A trained N. C. O. is in attendance night and day in every Canadian orderly room in England to see that the soldier carries out instructions so as to protect himself, and these instructions are clearly set forth on the walls of the room. In London there are two early treatment centers—at Southampton Street and at Victoria—and if not in the neighborhood of these centers, the men are instructed to go to an Australian or a New Zealand center. The Dominions are working together on this matter and are appointing centers throughout the United Kingdom, which are open to men from any of the British Imperial Forces. In this work the fact that absolute immunity cannot be assured, even though preventive measures are taken, is emphasized. Otherwise, the methods adopted might lead to an increase in the spread of disease, as has actually happened in Germany. The penalty exacted in the case of the Canadian soldier is the suppression of half pay during the entire period that he is on the sick list. The venereal record is also inserted in his medical history and accompanies him throughout his military career. Colonel Adami points out that, contrary to the generally accepted view, experience at the special hospital at Witley camp has

shown that physical training materially shortens the period of hospitalization in acute gonorrhea. As a result of the campaign against venereal disease, its incidence among Canadians in Great Britain has been reduced from 960 cases among 42,000 men in 1916 to 750 among 110,000 men in 1918, or more than 66 per cent. As to the effect of the return of the soldiers upon the venereal incidence throughout the country, Colonel Adami draws attention to the fact that it is not the civil population that has to fear the soldier, but the soldier the civilian. A Wassermann test is made in the case of every returning soldier whose medical sheets show a record of venereal disease and the figures for the month of August show that only 2 per cent. of the total number of men reacted, whereas in the civilian population the average number of reactions is from 8 to 12 per cent. During the four years of war nothing has been done to meet the emergency. The provision of early treatment centers throughout the country is an impossibility, at any rate before demobilization has become a matter of history. In the author's opinion, therefore, the only way of preventing a tremendous increase in the number of cases of venereal disease throughout the country lies in providing the soldier, before demobilization, with the means of prophylactic treatment, with information as to how to obtain the same without difficulty, and by giving him precise instructions as to the method of employment.

December 23, 1918.

Addison's Disease and Sclerodermia.—M. Gerson describes the remarkable results obtained by treatment of this affection with adrenalin. He believes that in one of his cases he produced a generalized pigmentation, by the exhibition of thyroid tablets, of the Addison type. Sclerodermia enters the class of diseases due to vagotonia of the Vienna school and in some cases of this affection the writer refers to the relations existing between the vegetative nervous system and the endocrine glands. He was able to note that, in the vagotonias, the pigment metabolism might be influenced by four factors, namely, pregnancy, sclerodermia, thyroid products and locally by lesions of the nerves.

Polycythemia Rubra.—H. Zeller relates the case history of a typical essential polyglobulia (Vaquez's disease) with a slight splenomegalia but without hypertension. The case does not differ from many others already published excepting the presence of myelocytes in the blood, which would seem to indicate a state of irritation of the red bone marrow.

Left-Handedness.—H. Siebert recalls the distinction that has been made between "essential" left-handedness and the "occasional" form, the latter resulting from an encephalitis or other lesion of the left hemisphere in childhood. Both forms can be distinguished by a sign that Siebert has been able to verify, namely, that true left-handed subjects learn to write mirror writing with the greatest ease with the left hand, this faculty increasing with advancing years. Four cases of left-handedness following an organic cerebral lesion studied by the writer, presented, on the contrary, a marked incapacity for this exercise. The writer also insists on the lesser differentiation of the lower limbs so that both left and right-handed subjects offer less difference in their control of the leg movements.

December 17, 1918.

Gunshot Wounds of the Diaphragm and Diaphragmatic Hernia.—Oberndorfer gives a detailed account of six cases of traumatic diaphragmatic hernia with figures. The writer's conclusion is to always look for this lesion in wounds of the lower left thoracic wall. The diagnosis cannot usually be made without radioscopy.

Traumatic Eventration of the Stomach Into the Left Hemithorax, with a Clinical Picture of Hypertensive Pneumothorax.—W. Lehn shows that, besides traumatic diaphragmatic hernia, which tends toward chronicity and may even be well borne by the patient, there is also an acute syndrome following the initial lesion. In the case reported by the writer there was a tangental tear of the left diaphragmatic dome from a shrapnel bullet. An intense dyspnea and cyanosis arose within a few hours following the receipt of the injury, the heart was forcibly pushed to the right while the left thorax became immobilized in the position of expiration, giving a marked tympanic note. The diagnosis was uncertain and the question of operation was under discussion, when the patient settled all controversy by making his exit from this world. At autopsy it was found that the entire stomach had passed into the left thoracic cavity, this having been favored by the patient's respiratory efforts which became more and more intense as the displacement of the stomach and heart progressed.

Diaphragmatic Hernia Becoming Strangulated in an Old Gunshot Tear in the Diaphragm.—E. Seifert reports a successful operation for this pathologic condition.

Positive Wassermann in the Cerebrospinal Fluid in Non-Luetic Meningitis.—C. Kraemer and Zadek record five cases of meningococcic, pneumococcic or tuberculous meningitides in patents where syphilis could be excluded both from the antecedents and autopsy and where a Wassermann of the blood was negative. The writers endeavor to explain the positive Wassermann of the cerebrospinal fluid in these cases by the presence of antilipoid ferments in the fluid, without being able to explain why this phenomenon should be more frequent in septic meningitis than in the tuberculous variety where a positive Wassermann is very much less common.

December 19, 1918.

The Mechanism of the Action of Cleansing Substances.—J. Geppert questions whether or not the mechanism of cleansing resides in a dissolution or in an emulsion of dirt from the action of soap and water. He concludes that such explanations are insufficient and in their stead invokes the action of capillarity. Water, alkalis and soaps are bodies which adhere to the object to be cleaned and thus remove the insoluble dirty matter. Just as in a test-tube water will insinuate itself between the walls of the glass and an oily content forming a meniscus with an upward concavity, in a like manner water has a tendency to become substituted for dirt on a bit of tissue or the cutaneous surface. The writer has microscopically verified this mechanism of mechanical washing as well as the influence of the nature of the texture; for example, tissues with fine meshes are more difficult to wash on account of the greater capillary adhesion of dirty matter to the fibers. The writer ends by giving some data on the way different fatty acids and oleaginous substances behave in this respect.

Meiniche's Serodiagnosis of Syphilis.—Von Vagedes and Korbsch have noted that the procedure of floculation gives results in accord with the Wassermann. Meiniche's procedure is to be recommended on account of its simplicity, especially when guinea pigs cannot be obtained. However, the Wassermann remains indispensable for the examination of the cerebrospinal fluid and serahemolysis.

The Struggle Against Typhus Fever.—Jürgens refers to the danger of a pandemic of typhus now that demobilized troops are returning to Germany. He outlines rules for the prevention of extension of possible foci of the disease and for assuring attentive care for every case. The certitude of being well cared for will bring the patients to hospital as soon as they feel ill, but if too severe measures for isolation of the cases are adopted the people will hide their disease as long as they possibly can.

December 7, 1918.

The Choice of Isoquinolinic Alkaloids (Isochinolinalkaloide) of Opium and Emetine, and Their Therapeutic Uses.—J. Pal recalls the fact that these alcaloids diminish the tonus of the unstripped musculature and therefore are of appreciable utility in the treatment of certain painful spasms (arteries, bladder, intestine, etc.). The writer, however, shows that this hypotensive action

is not accompanied by an increase in the lumen of these hollow organs. The chemical parenty of emetine with the alcaloids of opium caused Pal to experiment on their therapeutic substitution. Thus papaverin and narcotin possess a dilating action on the bronchial tubes as does emetine, but are devoid of the fluidifying action on the bronchial secretions. Papaverin, like emetine, has a decongestive action on the lesser circulation, an action which can be utilized in hemoptysis. In dysentery, the writer has noted an action of papaverin quite as efficacious as emetine, especially from the viewpoint of the control of rectal tenesmus. He likewise gives an outline of the reciprocal use of these divers alcaloids.

The Radiodiagnosis of the Consolidation of Fractures.—R. Lenk shows that the distinctness with which a callus can be seen does not indicate the solidity of the union, since a callus is more the evidence of the gravity of the fracture than evidence of its resistance. The writer proposes to manipulate the limb while observing the callus on the radioscopic screen. The degree of immobility will allow one to judge the amount of consolidation obtained.

Le Progrès Médical.

December 21, 1918.

Hexamethylenamine and Methylene Blue in Grippe.—Loeper and Grosdidier refer to a number of favorable reports on the intravenous administration of hexamethylenamine in influenza. The authors were, however, the first to make use of it and take this opportunity to state that in doses which aggregate 2 to 3 grams daily the drug is antithermic, sedative, and diuretic. They are convinced that this treatment will prevent and abort but not cure bronchopneumonia in a good percentage of grippe victims, while admitting that it sometimes fails perhaps more in streptococcic than other cases. When its action is positive, it is prompt and decided so that in failure there is time for other treatment. The authors are not partisans of the view that hexamethylenamine acts by the liberation of fomol, a bactericidal substance. Its beneficent activity they ascribe solely to its action upon the kidneys in stimulating the elimination of the disease virus. In confirmation it is added that it is the patient who shows prompt diuresis who recovers. There is some danger that too large initial doses may aggravate the albuminuria which is so common in these cases, so that it is best to begin with a low dosage and increase as rapidly as possible. In the case which does not respond to this drug methylene blue appears to give positive results. In 13 out of 20 cases of bronchopneumonia the authors saw recovery take place under methylene blue given by the mouth in usual dosage. In their experience the intravenous method was in no wise superior to the buccal route, and they therefore preferred the latter as being by far the simplest and absolutely free from danger. They would reserve this remedy for the bronchopneumonias of grippe just as they would employ hexamethylenamine for the first stages of the simple and toxic forms of the disease.

Bulletin Général de Thérapeutique.

December, 1918.

Treatment of the Pandemic of Grippe.—The editor gives a full picture of the various attempts in different parts of the world to prevent and cure influenza. He begins with plain, every day grippe and with its prophylaxis. This is bound up in isolation and segregation and in prevention of assembly by the public, in the disinfection of public buildings and transportation vehicles, in hygiene of the mouth and throat with antiseptic applications and the use of masks. Vincent would protect the eyes, believing that the spread of the disease may be traced to the ocular discharges. The author believes firmly in vaccination and for the present would make Pfeiffer's bacillus responsible for infection and strive to immunize against it. Under cure of simple grippe he recommends quinine as hydrobromate in connection with the usual aspirin or equivalents, and phenacetine. Given alone the latter drugs cause perspiration and otherwise appear to depress, so that he would combine quinine with aspirin. For persistent fever he recommends hydrotherapy. He believes in the colloidal metals and in heart stimulants like adrenalin and strychnine. A small quantity of alcohol is allowable. Under influenza with complications and increased severity, of course, he makes the statement that autotherapy has been tried extensively in these cases, whether with blood serum or blister serum. Injection of convalescent serum from others is advocated in this connection. Serotherapy against the various cocci of secondary infection is also used. These resources may be employed to prevent complications, while for cure after complications have developed the author believes in the various colloidal metals—the colloidal solutions of tin and arsenic have been used of late by competent authorities, while fixation abscess is another resource. In treating chest complications we must ask: "are we menaced by pneumonia or edema of the lungs?" It is often in the fulminant case that we have no absolute means of judgment. We may combine these fulminant cases under the name of asphyctic grippe. In such cases we cannot do much with drugs, unless they are given by intravenous injection, as their absorption when exhibited per os would be very problematical. Copious venesection followed by saline infusion is our only recourse unless Vincent's hot baths prove of value. The author is silent as to camphor in this connection.

Il Policlinico.

December 18, 1918.

Influenzal Pneumonia and Pestous Pneumonia.—Dragotti refers to the frequency and severity of pneumonia in widely separated epidemics of influenza during the past year, which led many to ask soberly "is not this affection true pestous pneumonia?" It was evident that on the furthest Eastern fronts of battle severe affections of the troops were pardonably placed in hypothetical connection with the bubonic plague and not only the rank and file, but people of class were by no means certain that the lung pest had not gained a foothold in Europe. The bacteriologists quickly and finally placed the quietus on all such reports, but all men are not yet convinced that some occult connection between the two pestilences does not exist. In regard to anatomical appearances but few Italian pathologists have personal knowledge of the lung pest. Despite alleged great similarities in the finds, no buboes have been seen anywhere. This fact, together with certain dissimilarities in the affected lungs, constitute strong testimony for the dualist, but the unicist is not wholly convinced because the pandemic has not subsided and something may yet appear to support his contention. In this connection the author cites the finds of Symmers of New York as to the many analogies and the few points of difference in autopsy lung finds. On the other hand, De Brume of Paris, who has evidently taken care of both types of case, speaks of clinical differences. The cough in the lung pest is unique and has not been seen in influenza. There is one paroxysmal expiratory effort every ten or twenty seconds which persists even through much of the night. With all of this cough we see very little expectoration and then very inoffensive looking, although swarming with pest bacilli. Only occasionally is the sputum abundant and rusty. Dyspnea and cyanosis are constant and largely unmotivated as in fulminant influenza without frank pneumonia. In many cases at least the lungs on physical examination are nearly sound and the heart suffers but little if at all—these people do not die by the heart. But in the secondary pneumonia of the bubonic plague the phenomena differ from pestous pneumonia as a primary affection. Further clinical comparison between influenza and lung pest reveals numerous dissimilarities. In the latter there is no delirium and the mind is clear to the last. In conclusion the greatest similarity is in anatomical finds, while extreme dissimilarity is seen in both bacteriological and clinical aspects. To this add the differences in epidemiology and the unicist has little to sustain his viewpoint.

Book Reviews.

COMPENDIUM OF HISTO-PATHOLOGICAL TECHNIC. By EMMA H. ADLER, Formerly Technician Pathological Laboratory, Presbyterian Hospital, New York. Price $1.25. New York: Paul B. Hoeber, 1918.

THIS is a useful little compendium of histological technic. It is intended for the use of the student untrained in laboratory work and should well fulfill this purpose.

WAR SURGERY OF THE ABDOMEN. By CUTHBERT WALLACE, C. M. G., F. R. C. S. Eng., M.B., B.S. Lond. Surgeon, St. Thomas' Hospital; Lecturer on Surgery in the Medical School; Consulting Surgeon, British Armies in France. Pp. 152, with 26 illustrations. Price, $3.00 net. Philadelphia: P. Blakiston's Son & Co., 1918.

WHILE this book appeared too late to aid in the training of many American surgeons for war service, fortunately it is a book whose value does not cease with the signing of the armistice but will be of value in solving certain problems in civil practice also. Based upon the author's experience as Consulting Surgeon to the British Armies in France, and with the utilization of material drawn from a sector of the battle line over a period of 30 months, naturally the methods recommended and the conclusions drawn are of much more than ordinary interest, particularly since the author's statistics are based upon the careful study of nearly 1,000 operated cases.

The introductory chapter discusses the utility of former experiences in war surgery, methods of treatment in the earlier periods of the war, and various other subjects bearing upon actual war problems. The second and third chapters also are largely concerned with the surgery of war rather than of wounds received under such conditions as might obtain in civil practice. The remaining chapters, however, contain much material of the greatest value to the civil surgeon who may have to deal with gunshot and other abdominal injuries, and have the following headings: "Diagnosis and Treatment Considered Generally; Wounds of Hollow Alimentary Organs and Their Treatment; Wounds of Solid Alimentary Organs and Spleen; Genito-Urinary Organs; Abdomino-Thoracic Wounds and Diaphragmatic Herniæ; Causes of Failure; and Statistics, Results and the Future."

Wallace finds that experience has shown the wisdom of operating as a routine measure in abdominal cases; but that there are some exceptions, such as, (1) Cases in very bad condition; (2) Cases shot high up in the abdomen in the liver area; (3) High abdomino-Thoracic wounds on the left side; and (4) Cases arriving late—after 24 hours. In some of these classes, especially the first, the question of operation is a matter for the individual surgeon to decide. In these, he says, the pulse will be a valuable guide and the bolder surgeon may get the worse operative mortality and yet save more lives. In considering wounds of individual organs statistics are given showing results under different methods of treatment and with various methods of operative technique. These statistics should be of great value to surgeons in civil practice who are sometimes called upon to operate upon cases of gunshot wounds of the abdomen; while the text is filled with valuable observations and suggestions.

WAR SURGERY FROM FIRING LINE TO BASE. By BASIL HUGHES, D.S.O., M.A., M.B., B.C. (Cantab.), B.S.C. (Lond.), F.R.C.S. Temporary Major, R.A.M.C., T.F., and H. STANLEY BANKS, M.A., M.B., Ch.B. (Glasg.), D.P.H. (Cantab.), Captain R.A.M.C., T.C., with special chapters by Lieut. Colonel L. F. SMITH, C.M.G., R.A.M.C., and Miss C. BILTON, R.R.C., Q.A.T.M.N.S., and an introduction by Colonel Sir T. CRISP ENGLISH, K.C.M.G., F.R.C.S., A.M.S., Consulting Surgeon to the British Forces in Italy; Formerly to the British Salonika Force; Surgeon St. George's Hospital, London. Price, $9.00. New York: William Wood & Co., 1919.

THE title of the work expresses its contents. It is a description of the manner in which wounded soldiers were treated from the time they were first wounded until they were discharged. Only the newer methods are discussed. The authors are peculiarly well adapted for the writing of such a work, as their experience was gained from three and a half years' work on both the Eastern and the Western Fronts, during which time they were engaged in all the different kinds of surgical service that fall to the lot of an army surgeon in war time.

Gunshot fractures are dealt with at considerable length and the subject is handled from all angles. It was found that the Carrel-Dakin treatment, when properly and systematically applied to war wounds, gave the best results. The chapters concerned with the conditions peculiar to airmen contain a good deal of valuable and interesting matter and it is pointed out that the immediate danger of wounds inflicted on men whilst flying is uncontrollable and rapid hemorrhage, due to the rarefied state of the atmosphere.

The authors found that superficial wounds caused by hand grenades and into which dirt and very small fragments of thin metal had been driven were best cleaned by scrubbing with hydrogen peroxide. Messrs. Hughes and Banks appear to be in favor of mechanical means for keeping fractured limbs in place, and little mention is made of passive and active movements in the treatment of broken limbs. The treatment of burns is considered at length and it is stated that paraffin wax is the best dressing for burns if applied within an hour or two of the injury.

Lieut. Col. L. F. Smith contributes a chapter on the effects of climate and certain diseases on wounds with diagnosis and treatment, and Miss C. T. Bilton writes regarding nursing on active service. The work is adequately illustrated. In fact, the colored illustrations are quite a feature of the book, being distinctly comical. It is not usual to inject humor into works on surgery. However, it is by no means a displeasing innovation. Some of the colored representations of the wounded remind one of Bairnsfather's cartoons. The object of the funny cuts may be to show that the British Tommy is cheerful and inclined to joke even in the most untoward circumstances. In any event, the colored illustrations certainly add to the interest of the work, and they are thoroughly correct in what they are intended to show in the way of splints and dressings. The book is thoroughly modern and eminently practical and shows how successfully wounds can be treated when a definite plan of campaign is laid down and strictly adhered to. It should be mentioned that the authors discuss the general health of troops while in the trenches, as they are convinced that prophylactic measures mean everything to the soldier when his day of misfortune arrives.

SURGICAL APPLIED ANATOMY. By SIR FREDERICK TREVES, Bart., G.C.V.O., C.B., LL.D., F.R.C.S. Eng. Sergeant Surgeon to H. M. the King; Consulting Surgeon to the London Hospital; Late Lecturer on Anatomy at the London Hospital. Seventh Edition. Revised by ARTHUR KEITH, M.D., LL.D. Aber., F.R.C.S. Eng., F.R.S. Hunterian Professor and Conservator of the Museum, Royal College of Surgeons of England; Formerly Lecturer on and Senior Demonstrator of Anatomy at the London Hospital; Examiner in the Universities of Aberdeen, Cambridge, etc.; and W. COLIN MACKENZIE, M.D. Melb., F.R.C.S. Edin., F.R.S.E. Member of the Council of the Anatomical Society of Great Britain and Ireland; Formerly Lecturer on Applied Anatomy, University of Melbourne. Price, $3.00. Philadelphia and New York: Lea & Febiger, 1918.

WHEN a book reaches a seventh edition it rarely needs favorable comment by the reviewer to stimulate its distribution. This is particularly true of Treves' Surgical Applied Anatomy; for it has enjoyed a constantly increasing popularity for 35 years and is well and favorably known to a large majority of all those who have studied medicine and surgery during that period. The present edition has been revised in the light of recent surgical experience. Many additions have been made, especially in the field of orthopedic anatomy, which is concerned with "the kind of knowledge which is necessary for the successful treatment of stiffened joints and disabled limbs." Twenty-seven new illustrations have been added. The book contains, in compact form, information of great value to the operating surgeon as well as the interne and the student.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 26, 1918.

DR. WILBUR WARD IN THE CHAIR.

The Visitations of Influenza and Its Influence on Gynecological and Obstetrical Conditions.—Dr. LILIAN K. P. FARRAR presented this communication, in which she first reviewed historical data which showed that epidemics of influenza had occurred from time to time for many centuries. She said that though the uncertain and fragmentary character of the oldest medical chronicles did not permit the absolute identification of influenza with the "Epidemical Diseases" of Hippocrates or with "The Plague of Athens" described by Thucydides, nevertheless, many historians believed them to be one and the same disease. Chronicles gave evidence that influenza was probably endemic in Italy from the Sixth to the Tenth Century, but it was not until the Twelfth Century that the epidemic character of the disease was recorded. Dr. Farrar cited evidence to show that since that time epidemics of influenza had at intervals swept over Europe, though the term "influenza" did not come into use until the latter part of the Eighteenth Century, and was formally adopted by the College of Physicians in London in 1782. Seven epidemics of influenza were recorded during the Eighteenth Century, and in 1780 a remarkable pandemic encircled the globe. The Nineteenth Century was marked by several epidemics in Europe, four in the Western Hemisphere and by three pandemics. The type of influenza of 1889 differed somewhat from previous invasions in that while catarrhal symptoms were present the prostration and ensuing weakness were the most marked symptoms; but the chief characteristic of this epidemic, which had made it unique in the long history of invasions was the recurrence of the epidemic in three successive seasons. The present epidemic of the Twentieth Century, while yet unwritten, had contributed a name to history—"Flu"—descriptive not only of the disease, but of its power of mobility. In closing this historical review Dr. Farrar cited several theories that had been put forth from time to time to explain this illusive, universal disease which swept in waves over the earth at intervals. The cause of the disease had been sought in something as phenomenal as the disease itself, something telluric or cosmic. A mysterious something was looked for in the air, in the variations of the atmosphere, the alterations in drought and moisture, in effluvia from the soil, emanations from animals, earthquakes, volcanic eruptions, comets, and the relations of astral bodies. A remarkable theory of modern times had been expounded by Noah Webster. He said: "It seems probable to me that neither season, earthquakes, nor volcanic eruptions are the cause of the principal derangements we behold in animal and vegetable life, but are themselves the *effects* of those motions and invisible operations which affect mankind. Hence catarrh and other epidemics often appear before the visible phenomena of eruptions and earthquakes, and influenza is the effect of some excess of stimulant powers to the atmosphere by means of the electrical principle; for no other principle in creation which has yet come under the cognizance of the human mind seems adequate to the same effects." Dr. Farrar then considered the influence of influenza on the genital tract in women. That it had a very definite influence on both gynecologic and obstetric conditions was recognized and recorded in earlier epidemics, even Hippocrates having commented upon it. The influence of a severe attack of influenza upon menstruation was to markedly increase the flow if the onset of the disease coincided with the regular time of the menstrual period. The consensus of opinion was that menstruation did not render the individual more susceptible to influenza, but if the disease occurred it would call back a menstruation after a normal period had ended several days before, or it would bring on a period before its time. In either case the flow lasted longer and was much more profuse than normally. The bleeding was hard to check and frequently lasted until the influenza symptoms subsided. Often girls of ten or twelve years had their first period during an attack of influenza. In the presence of influenza the tendency of chronic uterine or pelvic disease was to almost certain acute exacerbation of local infection. According to Mynlieff, Gottschalk, and others, the cause of uterine bleeding was an acute infection of the mucous membrane of the uterus, as in other infectious diseases, as cholera, smallpox, typhus, and typhoid, as a result (1) of intoxication of the blood; or (2) due to a reflex motor disturbance of the uterus by infection in the respiratory or gastrointestinal tract; or (3) the bacillus itself caused an acute hemorrhagic endometritis. In discussing the influence of influenza on obstetric conditions, the essayist stated that pregnancy did not seem to make the individual more susceptible to influenza. Abortion was likely to occur at any period of gestation, but more especially in the early months, as the ovum was then more readily cast off. Dr. Farrar discussed the influence of influenza during the latter months of pregnancy, during labor and the puerperium, and concluded as follows: "(1) Mild attacks of influenza have no influence on gynecologic or obstetric conditions. (2) Severe attacks of influenza produce menorrhagia and exacerbation of chronic gynecologic conditions. (3) Severe attacks often cause abortion, premature delivery, or still birth. (4) Labor is prolonged and tedious. (5) Pregnancy has an unfavorable influence upon the course of a bronchitis or pneumonia in influenza. (6) Induction of labor has no beneficial effect upon the course of influenza. (7) The chances of general infection are greater if influenza occurs during the puerperium.

The Occurrence of Epidemic Influenza in Pregnancy.—Dr. GEORGE W. KOSMAK read this paper, in which he said that we might well inquire into the salient features that presented themselves to an observer which might be of assistance in future years if similar plagues came upon us. Had we learned enough from the incidence of influenza complicating pregnancy to warrant us in advising vaccine as a preventive or curative procedure, or if the influenza went on to the production of pneumonia were we warranted by our experiences to put an end to pregnancy? In answer to these questions it was difficult to formulate specific conclusions and the individual observer could do nothing more than present what in his opinion was a safe method of procedure. In presenting his own observations, Dr. Kosmak said he did so with the admission that they were limited to his personal experiences, that he had not drawn on the observations of others, and, being personal, such observations must necessarily be limited in scope. He had observed considerable differences on the course of the recent epidemic of influenza in different classes of the population. Among a series of private patients who were previously in good health and well nourished the symptoms complex described as influenza did not pursue any different course in the pregnant woman than in the non-pregnant woman. The question of prophylaxis against influenza infection was brought forward by the importunities of many patients who had read or heard of these procedures. He felt that he could not advise them satisfactorily, and consultation with both medical men and serologists failed to convince him that the procedure was either necessary or desirable. This might seem an iconoclastic attitude to assume, but in view of the scant knowledge we possessed regarding the causative germ of epidemic influenza, he did not feel it proper to subject pregnant women to a procedure the ultimate effects of which were doubtful at best and which, among other things, might lead to a sense of false security. He considered it more important to advise pregnant women to avoid crowds, to isolate themselves immediately if evidence of nasal discharge, cough, etc., appeared, to wear face masks if there were any other cases of influenza in the immediate family, and to keep their mouths as clean as possible by frequent rinsing with a mild antiseptic solution. Regarding the influence of the influenzal infection on the course of a pregnancy, it was not possible to make any definite statement. Among the writer's private cases there was only one case of threatened abortion in a patient, a II-para, who was about four

months pregnant. She developed a typical influenzal attack, but without any complicating pneumonia, and bled slightly for almost a week. Rest in bed and the administration of small doses of codeine, in addition to the treatment directed to the influenza itself, were all that were employed, and the pregnancy went on. In this patient there was a history of bleeding in the early months of her pregnancy, so that the influenza could not be accepted definitely as a factor. In neither his private nor his hospital practice did the writer notice any additional cases of this kind, except in one hospital patient with pneumonia in whom abortion at the fourth month took place. In one instance a nephritis developed which it seemed fair to attribute to the infectious disease as nothing of this kind had been observed in the patient's previous pregnancies. There were no signs of abortion in this case. During the height of the epidemic, from the end of September until the middle of November, there were twenty cases of undoubted pneumonia admitted to the wards of the Lying-in Hospital. Among these sixteen ended fatally. Four of these women were admitted after having been delivered at their homes. The others were all at or near term, with two at four or five months and two at seven months. Of twelve admitted at term and undelivered, five living children were delivered among the cases which ended fatally; of these two died within one or two days. Both premature babies died. In addition to the cases with complicating pneumonia, a considerable number of women in the wards had symptoms of the prevailing illness. The cough was the most troublesome symptom, although in none of the milder cases were any definite physical signs present in the chest. The women in labor who entered with the disease were isolated in a corner of the ward and the bed curtains drawn, but none of the milder cases developed pneumonia, nor did they apparently infect any of the other women as no cases whatever developed in the wards. In attempting to obtain a definite picture of the above group of cases, the impression was given of an illness of extreme severity in which the chances of recovery were doubtful in almost every case. Comparing the pregnant, however, with non-pregnant cases, he did not believe we could find any great degree of distinction. Pneumonia in a pregnant woman was always a serious complication, but their cases at least did not show that relief from pregnancy contributed to their well being. Personally, he did not believe that in a single instance would any better outcome have resulted had steps been taken to bring on abortion or labor in any of these cases. In the patient in whom an abortion resulted this was complete and easy, and in those in whom natural labor came on interference was only necessary in one case, in which a median forceps operation was done as soon as the patient was fully dilated. Labor in these severe pneumonias, as in eclampsia, often surprised one by its rapidity and ease. So far as prognosis in the baby was concerned, the essayist did not believe that we should sacrifice the chances of the mother in any way by the induction of labor or the employment of operative delivery in order to save the child. As to the treatment of these cases of pneumonia complicating pregnancy, no diversion need be considered from the usual routine. In conclusion, Dr. Kosmak said that if he were asked what he would do as the result of his observations in this epidemic in cases of influenza complicating pregnancy he would unhesitatingly answer, "Treat the influenza and let the pregnancy take care of itself." He would not resort to the induction of abortion unless some other circumstances called for the same. It seemed to him that the patient needed all her reserve strength to combat the toxemia from the influenza or pulmonary infection, and as her life was at stake she should not be jeopardized by adding the extra burden of an induced labor.

Dr. Frank Oastler said that he did not pay much attention to the disease when it first appeared. Later when the reports came in from the base hospitals in respect to vaccination they were fairly encouraging, so he decided to try it inasmuch as it was found to be harmless. He vaccinated 346 persons, twenty of them being pregnant women, and among these only one case of influenza occurred. This might be simply a circumstance. After he saw more of the disease and saw people dying in spite of everything that could be done for them, he felt that one was justified in vaccinating pregnant women, and he then vaccinated twenty pregnant women and none of them had influenza. That, too, might be simply a circumstance. However, among 346 persons it would seem that there would have been more than one case if there was nothing in the vaccination. Menstruation was nearly always induced among the women with influenza; nose bleeding occurred frequently among the men. Many women aborted or went into labor. He had had two cases of abortion and two cases of labor in pneumonia, and all four patients died. Of the two cases close to term the two children lived, one of these being a post-mortem cesarean section. These children were extremely cyanotic and it did not seem for a time that they would live. Every case of pneumonia that he had seen during the epidemic, and he had had ninety-eight cases, died with the exception of two. All forms of stimulation were tried, but without any effect whatever. Dr. Oastler said he had many horrible experiences during the epidemic. For instance, in one family of seven the disease broke out on Wednesday and by Sunday only two of the family were alive. Under such circumstances one felt justified in doing anything to protect the people. This might be the same disease we had in 1889 and 1890, but the virulence of the organism was different from anything we had had before. He had in years past had cases of ordinary grippe during pregnancy, and of five or six such cases that he recalled only one aborted, and she had a pleurisy with empyema but all got well. During the present epidemic all died and there seemed to be no way of saving them or of relieving them in any way. He had used three vaccines and had had no bad sequelæ from any of these vaccines.

Dr. J. Clifton Edgar said he had watched these two epidemics, the one in 1889-90 and the present one, in both hospital and private practice. While there was tremendous prostration in the former epidemic, there was not the prevalence of pneumonia and there was not the mortality that we had in the recent epidemic. In their reviews both Dr. Farrar and Dr. Kosmak thought abortion had no influence on the course of the disease. At Bellevue they thought the induction of abortion might help, but after due consideration it was decided to leave these patients alone. Dr. Edgar said he had not used vaccines in families other than those in which there were pregnant cases. There were sixty-one cases of influenza complicated by pneumonia on his Bellevue service and of these forty died, a mortality of 66.6 per cent. It would be ridiculous to say that these patients left the hospital in good condition, for most of them were in deplorable condition and were turned over to social workers. Of the forty fatal cases four died undelivered and thirty-six died after delivery. Of the four dying undelivered, one died at the fifth month of her pregnancy, one at the seventh month, and one at seven and one-half months. A post-mortem cesarean section was done in one case and the fetus was dead. Of the thirty-six cases that died after delivery, three were received as post-mortem cases, two were delivered at the fifth month, seven at the sixth month, eight at the seventh month, ten at the eighth month, and six at the ninth month. The only possible hint that these figures gave was that the further on in pregnancy the patient was, the greater was the interference with the diaphragm and lungs and the higher was the percentage of pneumonias developing. The severity of the pneumonias was the most striking feature. It progressed so rapidly that in several instances it was scarcely possible to get the patients off the delivery table before they died. Many patients brought to the hospital in ambulances with well developed pneumonia died in twenty-four, forty-eight, or seventy-two hours. Another characteristic observed was the severe toxemia of the pneumonia, the early collapse with cyanosis, and the rapid progress of the disease, with death a few hours after labor. The extent of the consolidation had impressed the speaker forcibly, there being at first a small area of consolidation in the lobar cases and large areas of consolidation, sometimes the whole of one side, in the bronchial variety. The early pulmonary edema was very characteristic and there was an almost constant occurrence of still births. The ordinary treatment for pneumonia was practically a failure. The

best results were obtained with digitalis. In the presence of kidney complications or a toxemia of pregnancy the cases almost invariably terminated fatally.

Dr. JOSEPH BRETTAUER said that his experience with these cases during the brief period from October 6 to 16 was still vivid in his mind and the depression caused by it was still present. He saw ten cases during that time, all of which ended fatally. The history of one of these cases was applicable to all. A young woman, between twenty and thirty years of age, either at or close to term, severely cyanotic with labored respiration, but no very extensive signs of consolidation of either lung, a rapid pulse and a temperature varying between 103° and 106°; the child found dead in utero from twenty-four to thirty-six hours before the onset of labor. Labor progressed normally with but slight effect upon the general condition of the patient. The respiration post partum seemed somewhat easier for a few hours, but cyanosis increased and death occurred between twenty-four and thirty-six hours post partum. Subsequent to the above mentioned dates he saw several additional cases and observed a lessened virulency of the infection. None of these cases ended fatally. The results obtained by immunization with various vaccines were doubtful. If Dr. Oastler vaccinated 350 cases and found that only one of them contracted influenza, it would seem as though the procedure must be of value if his experience was statistically correct. Immunization was resorted to at Mt. Sinai Hospital, but the number was too small to justify any positive conclusions. One positive deduction was made, however, and this was that among those attacked by the influenza there was no decisive difference in the percentage of those who had been immunized and those who had not.

Dr. HIRAM VINEBERG mentioned that a major had told him his experience in a cantonment. Five hundred men were given vaccines and 500 others received no vaccines. Of the 500 men who did not get the vaccine 33 per cent. contracted the disease, while of the 500 who received the vaccines only about 11 per cent. contracted the disease.

Dr. GEORGE GRAY WARD expressed his appreciation of the papers and said that his experience was very similar to that of the other speakers. He related one sad case occurring near the end of the sixth month of pregnancy. This woman developed influenza and pneumonia with marked cyanosis and died within seventy-two hours. There were no signs of the onset of labor in this case. Several other cases in pregnant women he put to bed and treated symptomatically, and there was no disturbance so far as the pregnancy was concerned.

Dr. J. CLIFTON EDGAR said that he had used a number of methods of vaccination, but not in pregnant women. As Dr. Kosmak had stated, they felt that it might be better not to attempt vaccination in these women until they felt more certain of its immunizing value. In families in which there was a case of pregnancy he vaccinated everybody, from the furnaceman up, except the pregnant woman. He had vaccinated over 200 persons in families in which there was a pregnant woman and had been able to follow every person, and he did not know of any one who had contracted influenza; but 200 cases did not mean much. He hesitated to use vaccines in pregnant women for fear of miscarriage.

Dr. HIRAM VINEBERG related an interesting case that he was called to see out of town. The woman was three days post partum, was running a temperature, and was fairly ill. She had been seen by several medical men who diagnosed the case as influenza and thought the fever was due to that disease. It seemed to the speaker that the case was one of septic infection, and subsequent events showed that his diagnosis was correct. This case was cited to bring up the question as to whether others had been called in consultation to determine whether a case was one of influenza or sepsis.

Dr. KOSMAK, in closing, said that the discussion seemed to have hinged on the value of vaccination. His reason for not giving the vaccination was that it gave a false sense of security. On the other hand, mechanical prevention was very important. He felt that we knew so little in regard to the value of vaccination that he was not warranted in subjecting a pregnant woman to this slight procedure. Nobody would say that it would do any harm, but that was not enough. Vaccination among soldiers in camp, where they were under constant observation, was a very different proposition from vaccinating individuals whom we could not follow. Dr. Kosmak said he had been led to take up the question of inducing abortion in pregnant women with influenza because a wave of hysteria seemed to be sweeping over the physicians on the East Side and word was passed around among them that every case of influenza in a pregnant woman ought to be aborted, and that had led him to suggest a symposium on this subject. The marked cyanosis in these cases did not seem to be due to want of air in the lungs, since some of the patients had very small areas of consolidation and yet would be almost black. It was thought that they might have hemolytic streptococcus infection, and this was found to be true in one case, while one of the blackest cases was sterile. As to the manner of infection, many of the nurses and personnel of the hospital were ill with the disease, but no cases developed in the wards. When cases came in with the infection they were isolated at the end of the ward and the disease did not spread in the ward. It had been a surprise that the cases in which labor came on were just like eclampsia in that labor was easy, natural, and rapid. He felt confident that if the induction of labor had been undertaken with the introduction of bags, etc., the cases would have had a much more serious course than they did.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting Wednesday, January 22, 1919.

THE PRESIDENT, DR. B. FRANKLIN STAHL, IN THE CHAIR

Social Disease in the Army.—Dr. EDWIN S. COOKE said that the prevalence of venereal diseases in the National Army had been the cause of much anxiety to the officers upon whom devolved the care and training of the youths in the service. From the writer's experience during fourteen months in the venereal work of one of the largest cantonments of the Army in this country he was forced to the conclusion that it was the unsuspected sufferers from venereal indiscretion, but revealed by the exigencies of military examinations, who were responsible for aspersions cast upon the Army and Navy. The first means toward safeguarding the soldiers from infection after induction into service was the selection of remote sites for cantonments by which so much, apparently unnecessary, hardship was entailed upon the soldiers and their friends. The disproportion between infections acquired before and after induction was approximately 95 to 5. Certain organizations showed a still lower percentage of incidence while in service. Of the infections acquired after induction many were of only brief duration and in all, cure occurred more quickly than would have been the case in civilian life. Examination by dark field illumination was required in every case of an open lesion upon the genitals, and a routine Wassermann blood test was made upon every soldier admitted to the venereal wards of base hospitals. The military hospital treatment of syphilis consisted of courses of arsphenamine, mercury, and in latent cases, or when tertiary lesions were manifest, iodides, which necessarily caused considerable loss of time from active duty, and entailed upon the Government an enormous expenditure of money for drugs and in pay for the incapacitated soldiers. It was the rule in the Army not to deprive men of their pay while under treatment for venereal disease, provided they became infected prior to entrance into military service. By reason of the rigid enforcement of sanitation the incidence of ophthalmic infection had been reduced to a minimum. In the writer's experience not a single case of acute gonorrhœal ophthalmia arose in any of the wards under his care during the entire fourteen months of service. This record could be attributed to the admonitions of medical officers and attendants who were ever watchful lest an infected soldier should become lax and transfer the pus to his own eyes or those of others, and thereby subject the officers to reproach and a possible court martial examination upon the charge of negligence. As

contrasted with his civilian brother the soldier with social disease had by far the better of the argument, since he was not forced to hide his ailment, to treat himself with quack nostrums, or to prolong the malady by active exercise. It would seem therefore that the soldier was fairly well safeguarded and that it was rather the civilian population whose attention should be directed toward lessening the social evil.

Treatment of Early Stages of Syphilis.—Dr. Hiram R. Loux believed that with the early diagnosis of syphilis much could be done to prevent the rapid invasion and frightful sequelæ of this disease. All were convinced that there has been a percentage of cure by control. With the arsenical preparations a remedy had been found more speedy in its control possibly than was mercury. Excision of the sore did not prevent constitutional manifestations, but under careful examination the spirochætes were revealed and he believed it important that the general practitioner should be adequately equipped to make such examinations for early diagnosis. The State and municipal laboratories he said were available for the benefit of patients who could not pay for laboratory examinations, and he felt that if the profession at large could be induced to exercise particular care in such studies the percentage of the sequelæ of syphilis could be greatly reduced. He did not believe justice was done to patients unless in examinations there were checked up results in both the cerebrospinal fluid and blood tests. In the treatment of early syphilis there should be mapped out a régime of treatment as in tuberculosis. Why, for example, he asked, should one who had acquired syphilis be allowed to go about at will? Since it was known that in early syphilis the use of alcohol often destroyed the effect of treatment, why should it not be prohibited? Also, the labor of the patient should be regulated that his strength might not be overtaxed. The small and frequently repeated dose of salvarsan he had found to give better results than when the drug was given less frequently but in larger dosage.

Intraspinal Therapy in Syphilis.—Drs. Jay F. Schamberg and Albert Strickler said that their results in the intraspinal treatment of syphilis had convinced them of the indispensability of the method in appropriate cases. The paper presented the history of a group of cases so treated. No conclusive deduction, he said, could be drawn giving the reason why the combined intravenous and intraspinal injections effect better results than the intravenous alone. It might be that the blood serum sets up a mild aseptic meningitis and that this process increased the permeability of the choroid plexus to the passage into the spinal fluid of the arsphenamine charged blood plasma. Other physical conditions induced by the injection of the blood serum into the subdural space might likewise be operative. Dr. Francis X. Dercum was quoted as stating that he had seen on many occasions improvement in the symptoms of nerve syphilis brought about by the injection into the spinal canal of plain blood serum. Dr. Schamberg believed the query whether intraspinal treatment in syphilis would achieve that which could not be accomplished by other means was answered by the results obtained in patients in whom intravenous medication had been first tried with negative or mediocre results, and in whom combined intravenous and intraspinal treatment afterward brought about brilliant results. Case XVI was a striking example of this. The patient had had numerous intravenous injections of arsphenamine associated with the use of mercury and iodides administered in approved form. Not only was there no improvement, but the patient grew progressively worse and became incoherent and irrational. Thirty-six hours after the first combined intravenous and intraspinal treatment the patient's mind and speech suddenly cleared up, and had remained normal to the present time, a period of seven months. It was now realized, the speaker said, that syphilis might occur without any local lesion recognizable clinically as a chancre. If it were ultimately proved that there was a special strain of spirochetes having an affinity for nerve structure, it might possibly be demonstrated that infection with such strains induced relatively little reaction in cutaneous and mucous tissues. Another plausible explanation of unsuspected syphilis was that there might be a synchronous infection of gonorrhea and syphilis, the chancre being located in the urethra. Whatever the true explanation, the fact remained that there were encountered many cases of late syphilis in patients in good social standing who had no knowledge of a chancre or of any other antecedent manifestation. During the secondary stage or period of vascular diffusion of the spirochetes these parasites were carried to the central nervous system and either brought about inflammatory changes in a few months or years resulting in the exudative form of nerve syphilis, or in the course of years insidiously led to inflammatory and degenerative types such as tabes dorsalis and paresis. Regarding the limitations of intraspinal therapy, the author said one could never hope to restore degenerated nerve tissue. Paresis could not be cured unless treatment were begun at an extremely early stage. The most favorable time for treatment was before clinical evidence of paresis developed. A routine examination of the spinal fluid in all cases of syphilis would enable physicians to detect the pre-paretic stage by the spinal fluid findings. Systematic treatment at this time would doubtless prevent this unfortunate eventuality. The same statement was to a greater extent true of other forms of nerve syphilis which were more amenable to treatment. There were needed numerous well equipped institutions and well trained men to carry out the arduous work which such systematic examinations and treatments would entail.

Dr. William H. Mackinney urged that the only hope of avoiding grave constitutional manifestations and involvement of the central nervous system in syphilis lay in early diagnosis and treatment. To the genito-urinary man early syphilis meant the initial lesion and a negative Wassermann reaction. With the advent of a positive Wassermann there was late syphilis, a constitutional syphilis which invaded every organ in the body. There was only one stage of early syphilis, generally the first week or ten days of the chancre. Constitutional syphilis was present at the end of three weeks and not at the end of six weeks. Every sore not interfered with by mercurial washes or powders could be examined for spirochetes by the dark field illuminator in five or ten minutes. In all medicine there was no disease in which in connection with diagnosis a period of two weeks made so much difference as in syphilis. If a negative Wassermann were waited for one would wait until constitutional syphilis was present. Whenever possible without mutilating the part Dr. Mackinney excised the chancre. This did not mean anything in the way of cure but that there was removed a hard indurated area of infection which in all probability was not easily influenced by anything put into the man's body at any other part of his anatomy.

Dr. Alfred Gordon said that in a series of cases of neurosyphilis of great variety treated by the intraspinal method his results had coincided with those reported by Dr. Schamberg. In one case of a locomotive engineer who suffered with lancinating pain and ataxia there was entire relief following one treatment by the intraspinal method. In another case in which the patient was incapacitated he was able to resume his work after two treatments with an interval of two weeks. Dr. Gordon had obtained moderate improvement in early stages of paresis, but not in the late stages. Recalling the tremendous number of spirochetes to be observed in the meninges it was not to be wondered at that their removal was practically impossible.

Dr. F. X. Dercum said that in the diagnosis of all cases in which neurosyphilis was suspected examinations should never be confined to the blood tests. The examination of the spinal fluid was an absolute necessity. In the intraspinous treatment of syphilis in his own clinic, where the method was practised most extensively, drainage was much more freely done than by Swift himself. In paresis the most serious problems were presented and he had yet to see cases in which paresis had been cured. These patients might improve for a time and remain apparently well for years, but when the metabolic processes began to fail the spirochetes got the upper hand and then followed tabes and paresis. In the paretic case emphasis should be placed upon the importance of treating the general condition of the patient.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, January 1, 1919.

THE PRESIDENT, COLONEL RICHARD H. HARTE, IN THE CHAIR.

Reconstruction Program of the Public Health Service.—Senior Surgeon CHARLES E. BANKS, U. S. P. H. S., Washington, D. C., said that the writer of the history of the present war would find among the most significant of its developments the achievements of the medical profession in the field of preventive medicine; in the huge army of nearly five millions mobilized in the United States there had been less than 200 cases of typhoid fever. One might safely say that as a result of the remarkable work in sanitation and preventive medicine carried on by the allied medical organizations, hundreds of thousands of fighting men had been preserved from ignominious death from preventable disease. That which had been accomplished in the military zone under most unfavorable environments, the author said, could be duplicated in civil life under less complicated conditions. The men whose lives had been saved by the application of modern sanitary methods and the principles of preventive medicine understood the necessity for the application of sound sanitary principles to the ordinary daily walks of life. They would not only practise these principles themselves, but demand that those in authority in health matters should apply them in the interest of the public health. The superficial work which had characterized a good deal of the health activities in the past would be no longer tolerated. The medical profession must be prepared for a reconstruction of methods in connection with the public health. The saner logic of preventive medicine would supersede the ancient order of attempting to cure disease that has become established. The leadership in this period of reconstruction would naturally devolve upon the United States Public Health Service. The program with which this national organization intended to meet the emergencies of the situation was comprehensive and far-reaching and for its full success was dependent upon the cooperation of organized medicine. Such program, it was said, met urgent national needs by outlining health activities which were practicable and which would yield the maximum result in protecting national health and would diminish the toll of thousands of lives sacrificed by preventable disease and insanitary conditions. The program comprised exhaustive work under industrial hygiene, rural hygiene, prevention of the diseases of infancy and childhood, water supplies (national development of safe water supplies), milk supplies (national development of safe milk supplies), sewage disposal, malaria (national development of measures for its control), venereal diseases, tuberculosis, railway sanitation, municipal sanitation, health standards, health education, collection of morbidity reports, organization and training for duty in emergency of the Reserve of the Public Health Service. The speaker said if this great world war had found the nation unprepared, the same should not be true in this period of reconstruction.

Dr. J. M. ANDERS stated that public health activities had greatly suffered during the war, which was perhaps especially true of civilian tuberculosis activities, for the reason that many able workers were in the army and navy. Perhaps the most important of the lessons learned in the recent world war was the fact that the individual efficiency of the men on the firing line was the foremost factor in modern warfare. The large percentage of rejections, by the local draft boards, of the men called to the colors directed especial attention to the problem of physical education in this country during this reconstruction period. Every individual, it seems to him, should be taught how to promote his or her health and he believed this could be best accomplished in connection with public and secondary schools as well as in the colleges and universities. While the idea of universal military training should be encouraged, the scope of the plan should be, and the one presented to-night was, sufficiently comprehensive to include the entire American race. Dr. ANDERS believed that if in the immediate future sufficient attention were devoted to the matter of physical education many of the details in the program just outlined by Dr. BANKS would in due course be found to be unnecessary. All are probably aware of the fact that in England there had recently been formed a ministry of health which would combine and coordinate all the public health activities under one head. Such a reorganization of the public health activities in this country was reported as a consummation devoutly to be wished for, and which would certainly facilitate that which Dr. BANKS had emphasized, namely: The necessity of sympathetic cooperation among all allied agencies having to do with public health work. Moreover, he felt strongly that there could be no more propitious time than the present to set in motion efforts to such end.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 18, 1918.

(*Concluded from page* 310.)

GYNECOLOGY.

1. Differentiate irritable bladder from cystitis.
2. How would you manage septic abortion, incomplete, with hemorrhage?
3. What are the sequelae of a second degree tear of the perineum of years' standing?
4. Differentiate threatened abortion and tubal pregnancy at six weeks' gestation.
5. Give your technic in nephropexy.
6. Differentiate sarcoma of the ovary and fibroid of the uterus, tumors of the same size.
7. What are the following: Bartholin's glands; Gartner's duct; cysts of Morgagni; episiotomy?
8. Give operative technic and after care in cystocele, rectocele, in women of fifty years of age.
9. Describe the female urethra.
10. What are the symptoms of prolapsed ovaries?

SURGERY.

1. What are the indications for enucleation of the eye ball?
2. Give the diagnosis and surgical treatment of infection of the antrum of Highmore.
3. Describe the technique of an operation for the transfusion of blood.
4. What is a bunion and describe an operation for relief of same.
5. Differentiate between acute appendicitis and a calculus lodged in the right ureter at the brim of the pelvis.
6. Diagnosis and treatment of splenic anemia (Banti's disease).
7. Diagnosis and surgical treatment of chronic enlarged prostate in the aged.
8. Diagnosis of acute intestinal obstruction.
9. Diagnosis and surgical treatment of acute perforation of a gastric ulcer.
10. Diagnosis and treatment of fracture of the external condyle of the humerus.

MEDICAL JURISPRUDENCE.

1. Name the two classes of witnesses and differentiate.
2. Define cadaveric spasm and explain its importance in suicide.
3. Differentiate between male and female pelvis.
4. Define puerperal insanity.
5. Give signs of pregnancy.
6. Give difference between civil and criminal malpractice.
7. Differentiate between amentia and dementia.
8. What is a lucid interval?
9. Define cerebral neurotics and name two.
10. Give symptoms of carbolic acid poisoning.

ANSWERS.

GYNECOLOGY.

1. In *cystitis*, the symptoms are: Frequent urination, with tenesmus and a burning sensation in the

urethra; later on pain in the bladder, hematuria, and the urine contains pus and epithelial cells. Chills, fever, rapid pulse, and headache may also be present. A feeling of weight or pain in the pelvis is noticed. Cystoscopic examination will show an area of inflammation.

In *irritable bladder*, the symptoms are: Increased frequency of urination, with tenderness at base of bladder. There is no pus in the urine, and no inflammatory area will be found on cystoscopic examination.

2. In *incomplete, septic, abortion*, the uterus must be emptied at once; the cervix may need to be dilated, and a finger or curette may be used to clean out the débris. Irrigation with an antiseptic is next indicated; the uterus is then plugged with iodoform gauze, which is allowed to remain for twenty-four hours. Subsequent irrigations with saline solution or an antiseptic are required. Subsequent treatment is on the lines of that used in ordinary puerperal sepsis. Rest, stimulating food, tonics, and good nursing are imperative.

3. *Sequelæ of torn perineum*, are: Rectocele, cystocele, prolapsed uterus, loss of support of pelvic floor and viscera.

4.

ABORTION.	ECTOPIC PREGNANCY.
1. Onset quiet, with gradually intensifying and regular pains in the lower abdomen, resembling labor.	1. Onset stormy, with irregular and colicky pains, sometimes few and excruciating, localized on one side.
2. External hemorrhage profuse or moderate, with clots.	2. External hemorrhage slight or absent and dark fluid.
3. Symptoms of hemorrhage proportionate to visible blood-loss.	3. Symptoms of hemorrhage and shock much greater than visible blood-loss.
4. Discharge of parts of ovum.	4. Only a uterine decidua, if anything; no villi.
5. Demonstration of ovum in uterus or empty uterus and empty pelvis.	5. Finding of a mass alongside the uterus.

—(De Lee's *Obstetrics.*)

5. *Nephropexy:* "A lateral incision is employed, extending from just above the last rib nearly vertically down to the crista ilii; the muscles are divided; the last dorsal nerve is retracted and protected; and the kidney in its fatty capsule exposed and cleared. The upper half of the fibrous capsule is then dissected up from the posterior surface and carried round the last rib to serve as a sling to the kidney; the apex of this flap is secured to its own base. Two silkworm-gut stitches are passed under the capsule of the lower half of the organ in a semicircular fashion, and carried through the muscles and skin at the upper angle of the incision, being finally tied over a pad of gauze and retained *in situ* for three weeks. The wound is then closed in the usual way, and dressed, special care being taken to exercise pressure over the right iliac fossa below the kidney by a suitable pad of sterilized wool. The organ is thus firmly fixed, but it is wise to keep the patient in bed for four or five weeks subsequently, to allow of consolidation, and afterward a binder or belt should be worn for a time."—(Rose and Carless' *Surgery.*)

6.

FIBROID OF UTERUS.	OVARIAN TUMOR.
1. Slow growth.	1. Usually more rapid growth.
2. Facial expression unchanged. Face may be full and flushed; later pale from hemorrhage.	2. Facies ovariana in later stages.
3. General health not necessarily impaired except from loss of blood if submucous or mural; may be painful.	3. General health early impaired from emaciation. Not painful.
4. Abdomen often asymmetrical from irregular shape of tumor.	4. Abdomen more symmetrical, especially when tumor is large.
5. Usual menorrhagia.	5. Menstruation unchanged or diminished.
6. Vaginal touch and conjoined examination show tumor dense and firm, and, unless pedunculated, continuous with uterus. Uterus large and heavy.	6. Uterus normal, except displacement from pressure. Tumor separate from uterus.
7. Uterine cavity much elongated.	7. Not materially elongated.
8. Uterus moves with tumor.	8. Does not move with tumor.

—(From Dudley's *Gynecology.*)

7. *Bartholin's glands* are two small glands situated one on either side of the vaginal orifice.

Gartner's duct is a tube which extends (during fetal life) from the broad ligament to the wall of the uterus and vagina.

Cysts of Morgagni are structures sometimes found in connection with one of the fimbriæ of the Fallopian tube.

Episiotomy is a lateral incision of the vulva performed with the idea of enlarging the vaginal outlet and so preventing extensive laceration.

8. For the *rectocele*, "the patient is secured in the lithotomy position, and the vagina thoroughly exposed with retractors. An elliptical incision, one end of the major axis being close to the cervix, the other near the vulvar orifice, is made in the mucous membrane of the posterior vaginal wall, taking care not to cut deeper than the rectovaginal septum, lest the bowel be opened. The vaginal mucous membrane is then cautiously dissected off; the amount to be removed is estimated by the laxity of the parts and the degree of narrowing which the operator regards as necessary to meet the needs of the case. After removing the vaginal wall and securing the bleeding vessels the cut edges of the mucous membrane are brought into apposition by a continuous silk suture or interrupted suture of silkworm gut or such other material as the operator thinks well to employ. The patient is kept in bed for at least two weeks; her bowels are regulated, and the bladder should not be allowed to become overdistended. The sutures should be removed in about ten days." For the *cystocele*, "a similar procedure is carried out on the anterior vaginal wall. The bladder is very liable to be injured in dissecting off the mucous membrane, and is particularly liable to be punctured when the sutures are introduced."—(Sutton and Giles' *Diseases of Women.*)

9. *The urethra in the female* is about an inch and a half in length and its transverse diameter is about a quarter of an inch; it is embedded in the anterior vaginal wall; its direction is downward and forward, and its walls are anterior and posterior. It passes through the two layers of the triangular ligament. The external orifice is the narrowest part, and opens between the labia minora, immediately in front of the external orifice of the vagina, and about an inch behind and below the clitoris.

10. *The symptoms of prolapsed ovaries*, are: Pain, which is made worse on standing, walking, exercising, and during coitus, defecation or urination. The pain is in the iliac region or near the sacrum, and may radiate to the rectum, hips or thighs. There are menstrual disturbances such as menorrhagia and dysmenorrhea. Faintness, nausea, vomiting, hysteria, indigestion and neurasthenia may be present.

SURGERY.

1. The *indications for enucleation of the eye* are: "(1) Injuries of the ciliary region when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic irido-cyclitis, to prevent or cure sympathetic ophthalmia; (3) severe pain in a blind eye; (4) irido-cyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and dis-

figuring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind."—(May's *Diseases of the Eye.*)

2. Abscess of antrum of Highmore. *Symptoms:* "There is pain, tenderness on pressing over the canine fossa or on tapping the teeth of the upper jaw, and sometimes swelling of the cheek. The complaint of a bad odor or taste, the reappearance of pus in the middle meatus after mopping it away and directing the patient to bend his head well forward, and opacity on transillumination of the suspected cavity are signs which strongly suggest an affection of the maxillary sinus. The withdrawal of pus by a puncture through the thin outer wall of the inferior meatus of the nose with a fine trocar and cannula will establish the diagnosis. The *treatment* consists in opening and draining the antrum. If the infection is due to a carious tooth this should be extracted, the socket opened up and drainage established through it. If the teeth are sound the antrum is opened through the canine fossa and its walls curetted, after which the cavity is packed with iodoform worsted. To avoid the risk of reinfecting the cavity from the mouth, an opening may be made into the nose, by removing the anterior portion of the nasal wall of the antrum and part of the inferior turbinated bone, after which the incision in the buccal mucous membrane is closed with sutures."—(Thomson and Miles' *Surgery.*)

3. *Transfusion of blood:* "Crile has recently revived direct transfusion by anastomosing the radial artery of one individual with any convenient superficial vein of another. Under local anesthesia both artery and vein are exposed, tied below, and secured with an arterial clamp above. Each is then cut above the ligature and the adventitia of the central end pulled down and snipped off with scissors. The vessels may then be united by the Carrel method. Crile uses a little tube which has two grooves in its outer surface. The central end of the vein is pulled through the tube, turned back over it like a cuff, and held in place by a ligature which is tied in the second groove. The artery is next drawn over the everted vein and secured by a ligature in the first groove. The clamps are then removed and the anastomosis covered with a hot moist sponge, to relax the artery. The time the blood is allowed to flow depends upon the effects noted, but is usually from twenty to forty minutes. In acute hemorrhage and shock and in pathological hemorrhage direct transfusion has proved of value, but in blood diseases and toxemias it seems of little use. As there is some danger of hemolysis and agglutination the effect of the donor's blood upon that of the recipient should always be studied before transfusion. If, owing to lack of facilities or time (the hemolytic test occupies twenty-four hours), this cannot be done, intravenous infusion of salt solution should be employed. Transfusion may, of course, be performed later if such seems to be indicated."—(Stewart's *Surgery.*)

4. A *bunion* is an enlarged, thickened, and (sometimes) inflamed or suppurating bursa situated over the inner aspect of the metatarsophalangeal joint of the great toe.

Operation includes either osteotomy of the first phalanx or of the first metatarsal bone; or removal of the head of the metatarsal bone with part of the hypertrophy on the inner side, and turning of the bursa into the joint area in front of the bone. The bursa is now sutured in place.

5. In *appendicitis:* The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

In *impacted stone in the ureter:* Colicky pain shooting along ureter, tenderness over ureter, hematuria, anuria (if opposite kidney is blocked or diseased), abdominal tumor (persistent or intermittent). Urine contains crystals, blood, or pus. Prolapse of ureter into bladder. Skiagram shows stone. In the majority of cases the symptoms are simply those of renal calculus, and diagnosis is only complete on lumbar exploration and passing ureteral sound.

6. *Banti's disease.* The disease is *diagnosed* by the symptoms: "The disease begins with the enlargement of the spleen, and the patient may first complain of a 'lump' in the left side of the abdomen. There may be pain in the splenic region, and the tumor is found to be tender. Splenic friction may be heard. The enlargement is progressive, and may become very great, but the lymphatic glands are not enlarged. Anemia usually accompanies the enlargement, but may be comparatively late. The red corpuscles may fall to 3,000,000 per cmm., the hemoglobin being still more deficient, and the color index therefore low. The leucocytes are reduced in number. This stage may last for several years, and is succeeded by aggravation of the anemia, with attacks of hematemesis, followed by melena. Other hemorrhages may occur, as from the nose, gums, or kidneys. Finally the liver becomes cirrhotic, and the last stage may be marked by jaundice, ascites, and diarrhea."

Treatment: "The splenic origin of the disease is indicated by the effects of *splenectomy*, which in the early stages often results in cure, but in the later stages is of little avail. Iron and arsenic may be of use, and the *x*-rays have sometimes proved beneficial, but operation is the only hopeful treatment."—(Wheeler and Jack's *Practice of Medicine.*)

Talma's operation of omentopexy has been performed in combination with splenectomy.

7. Hypertrophy of the Prostate.

The *Symptoms* of an enlarging prostate usually begin with frequency of micturition, then some difficulty in the act of micturition, with diminution in the power of projection. Some pain and tenesmus occur later. Secondary changes in the bladder depend on the amount of obstruction. Hypertrophy and sacculation come on, and are followed by atrophy and dilatation. Dilatation of the ureters and hydronephrosis are produced still later. As atrophy of the bladder comes on, a certain amount of residual urine remains after each act of micturition. As this increases, distension and atony are found with overflow incontinence. Cystitis soon comes on, and may be followed by septic changes in the kidney. The early changes may be unnoticed till overflow incontinence appears. Priapism may occur in the early stages.

The *Diagnosis* is made by a consideration of the symptoms and physical examination. The gland may be felt to be enlarged from the rectum, but there may be marked prostatic obstruction with little posterior enlargement. The length and direction of the urethra are measured by a coudé catheter, and the amount of residual urine is noted.

The *Complications* which may occur are the following: retention, cystitis, calculi, hematuria, urethritis, and prostatic abscess.

Treatment is either palliative or operative, according to the indications present in the individual case.

Palliative measures consist in attention to the general health and avoidance of alcohol, exposure to cold, and excessive exercise. If there is any residual urine, the bladder must be emptied regularly by a catheter, either coudé, bicoudé, or silver prostatic; in catheterizing great care must be taken to make certain that the instrument is always aseptic.

Prostatectomy is conducted through a suprapubic cystotomy. The mucous membrane is torn or cut through all round the urethral orifice. A finger is then introduced, and by working all round with it the prostate is shelled out from its true capsule, leaving the urethra intact. A gum-elastic catheter is kept in the urethra during the operation, and the left forefinger is kept in the rectum to push up the prostate and help the right. The cavity is washed out with saline solution and drained by a tube through the suprapubic wound for five days. No catheter need be passed. Some cases die from hemorrhage or sepsis, but the others recover the power of micturition, and have no further trouble.

The prostate may also be enucleated by a perineal incision.—(*Aids to Surgery.*)

8. *Intestinal Obstruction:* For the diagnosis of the several forms of intestinal obstruction see the table on the following page.

STRANGULATION	INTUSSUSCEPTION.	TWISTS (VOLVULUS).	CHRONIC INTESTINAL OBSTRUCTION.	APPENDICITIS	PERITONITIS
Subjective Symptoms.	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*	*Subjective Symptoms.*
1. Generally occurs after age of 20.	1. Most frequent in childhood.	1. Most frequent after age of 30.	1. Middle life.	1. Most cases occur before age of 25.	1. Usually in middle life.
2. Pain localized, rapid collapse.	2. Constant tenesmus.	2. Pain diffuse.	2. Pain diffuse, but comes on gradually.	2. Pain often develops rapidly.	2. Pain develops suddenly.
3. Pain intense, paroxysmal in character.	3. Pain develops suddenly and is continuous.	3. Pain paroxysmal; recurs less often than in strangulation.	3. Pain continuous.	3. Pain continuous	3. Pain continuous.
4. Constipation complete.	4. Frequent diarrhea, passage of bloody mucus.	4. Constipation complete.	4. Constipation complete.	4. Stools infrequent.	4. Stools infrequent.
Objective Symptoms.	*Objective Symptoms.*	*Objective Symptoms.*	*Objective Symptoms.*	*Objective Symptoms.*	*Objective Symptoms.*
1. Temperature often subnormal.	1. Temperature normal or subnormal.	1. Temperature slightly elevated.	1. Temperature moderate; frequently high.	1. Temperature moderate; frequently 104° F.	1. Same as in appendicitis.
2. Pulse very weak.	2. Same as in strangulation.	2. Same as in strangulation.	2. Pulse of good volume.	2. Pulse of good volume.	2. Pulse usually of high tension.
3. Stercoraceous vomiting comes on early.	3. Same as in strangulation.	3. Same as in strangulation.	3. Stercoraceous vomiting comes on after first few days.	3. Same as in intestinal obstruction.	3. Vomitus greenish; rarely stercoraceous.
4. Location in small intestine.	4. Localization in small intestine; bowel frequently protrudes at rectum.	4. Location, small intestine; abdomen often protrudes, in certain areas, giving dulness on percussion.	4. Location in large intestine; dulness on percussion.	4. Location in right iliac region; dulness on percussion.	4. Diffuse inflammation; tympanitic resonance.

—(*Pocket Cyclopedia.*)

9. *Acute perforation* of a gastric ulcer is announced by "sudden violent pain in the epigastrium, which often radiates to the back, up to the left shoulder, and down into the right iliac fossa. There are great tenderness, marked rigidity of the abdominal muscles, and shock of varying severity. There may be absence of liver dulness and movable dulness in the flanks. In about half the cases the stomach contents are vomited, but rarely is there any blood. In 10 per cent. of the cases there is no previous history of indigestion. There may be a leucocytosis.

"The *treatment* is immediate abdominal section, any existing shock being combated while the preparations for operation are under way. The incision is made in the middle line above the umbilicus, the perforation closed by a double row of Lembert's sutures of silk without excising the ulcer, the abdominal cavity cleansed with salt solution, and a gauze drain passed down to the vicinity of the perforation. If there is a generalized peritonitis, a second incision should be made above the pubes and the pelvis drained. In cases in which suture is impossible, the opening may be closed by the omentum, a loop of intestine, or gauze packing. The possibility of a second perforation should never be forgotten. Some surgeons perform gastroenterostomy at the time the perforation is closed, a practice which must necessarily increase the mortality, which, at present, is between 40 and 50 per cent."—(Stewart's *Surgery.*)

10. *Fracture of the external condyle of the humerus.*—"Examination shows localized pain, tenderness, swelling, and in some instances contusion of the soft parts over the external condyle. In addition there will be found crepitus, mobility of the condyle if the detached fragment is large, possibility of hyperadduction, and occasional displacement of the fragment upward. When the last condition is present, hyperabduction of the forearm is possible and a condition of cubitus valgus may be obtained. When marked displacement of the fragment is present the roughened edge of the large fragment may be felt. Widening of the joint may be present. Dislocation backward of the ulna may be present as a complication." *Treatment* consists in reduction, and retention by hyperflexion and supination; "an assistant should grasp the arm firmly, steady it, and at the proper time make counter-traction; the surgeon should first hyperextend the elbow-joint, separate impacted fragments, and then, by means of manipulation, engage the ends of the fragments; when this procedure has been accomplished, direct traction should be made upon the condyles; internal rotation should be corrected and the elbow slowly flexed, hyperflexed, and the forearm supinated. The degree of hyperflexion will depend upon the amount of swelling present. In cases of much swelling it is always wise to abstain from using flexion for a few days. As a rule it should stop at the point which causes discomfort or which is likely to cause compression of the brachial artery. The radial pulse should always be felt, after the bandage or other dressing has been applied, and an unobstructed beat of the radial artery proved to be present. An adhesive plaster strap two inches in width is applied by placing its center over the upper outer surface of the arm, and the two ends are then carried around the extensor surface of the supinated forearm at a point about two inches above the radial styloid. A wrist sling made of a cotton roller bandage surrounded by rubber tubing may be used to support the limb. The hyperflexion and supination should be maintained for at least three weeks. The dressing should be inspected every other day during the first week and twice weekly during the succeeding two weeks; it should be changed whenever necessary. The hyperflexed position is decreased slowly, and passive motion and massage are employed."—(Roberts and Kelly's *Fractures.*)

MEDICAL JURISPRUDENCE.

1. An *expert* witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by one perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness. A *non-expert*, or *material*, witness testifies only to the *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

2. *Cadaveric spasm* is a condition in which strong muscular contraction occurs at the moment of death; it is found in cases of sudden, violent death. It passes off, and the usual cadaveric rigidity may succeed it. It is often observed in cases of suicide, where the weapon is found firmly grasped in the hand of the dead person. It is evidence against homicide, and in favor of suicide.

3. The chief differences between the male and female pelvis are thus tabulated in Morris's *Anatomy:*

MALE.	FEMALE.
Bones heavier and rougher.	Bones more slender.
Ilia less vertical.	Ilia more vertical.
Iliac fossæ deeper.	Iliac fossæ shallower.
False pelvis relatively wider.	False pelvis relatively narrower.
True pelvis deeper.	True pelvis shallower.
True pelvis narrower.	True pelvis wider.
Inlet more heart-shaped.	Inlet more oval.

MALE.	FEMALE.
Symphysis deeper.	Symphysis shallower.
Tuberosities of ischia inflexed.	Tuberosities of ischia everted.
Pubic arch narrower and more pointed.	Pubic arch wider and more rounded.
Margins of ischiopubic rami more everted.	Margins of ischiopubic rami less everted.
Obturator foramen oval.	Obturator foramen triangular.
Sacrum narrower and more curved.	Sacrum wider and less curved.
Capacity of true pelvis less.	Capacity of true pelvis greater.

4. *Puerperal insanity* is a form of insanity which attacks women soon after childbirth; it generally occurs before the cessation of the lochia, and the patient frequently has a strong homicidal mania against the child.

5. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

6. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil malpractice.* But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

7. *Dementia*, or, as it is commonly called, *softening of the brain*, is a term which is applied to a condition of mental enfeeblement gradually increasing until it reaches a stage of absolute mental decay.

Amentia is a congenital condition, or comes on very early in life before the mind has fully developed.

8. *A lucid interval* (in insanity) is a period in which there is a temporary cessation of the insanity, or a complete restoration to reason.

9. *Cerebral neurotics* is the name given to a group of poisons which have a specific action upon the brain; they cause headache, drowsiness, delirium, coma, convulsions or paralysis. *Two examples:* Opium and alcohol.

10. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Endocrinous Function of the Nasal Mucosa.—According to Volpe histological studies of the pituitary membrane show certain formations termed by him siderophile granules, which are analogous to formations in the adrenals of the same name. These granules occur in hypertrophic and hyperemic epithelium, especially where bloodvessels are near at hand. They are colored by iron particles and strongly resist discoloration. Fuchsinophile granules are also present in both surface and glandular epithelium, corresponding to similar formations in secretory glands. Volpe believes that this double cell content indicates a double secretory action, internal and external.—*Archives Médicales Belges.*

The Descent of Man.—Fritsch has described the scalp hair of the higher apes in contrast with that of the different races of mankind. In the anthropoids the scalp hair differs in no wise from that of the surface at large. The reverse is true in man. To descend to detail, the wool of the negro in no wise resembles the scalp hair of the gorilla. The fine, red scalp hair of the orang is equally unlike the coarse, black Mongolian hair. These dissimilarities seem to clinch the belief that man did not descend directly from the anthropoids.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Pearls and Blindness.—As an example of pseudology the following appeared in a French periodical during 1837. A certain man swallowed a pearl by accident, and immediately went blind. The most celebrated oculists could do nothing for him and he drifted to the care of a notorious chalatan, who gave him a violent course of emetic treatment, at the close of which the pearl was ejected, whereupon vision at once returned. after 15 months' blindness. Naturally the fact that a swallowed pearl could hardly be expected to sojourn in the stomach for any considerable interval and would almost certainly have passed by the bowels in a very short time deprives the story of any credibility, irrespective of the coming and going of blindness. But an enterprising practitioner apparently or actually gave full credence to the story, and having caused to be made a fluid which contained pearl substance began to use and recommend it for practically all diseases of the eye, upon the theory that what is homeopathically sovereign for blindness could hardly fail to benefit lesser ills of the eye.—*El Siglo Médico.*

Miscellany.

Vaccine and the Grip.—In 1914, shortly after the outbreak of war, we noted in an anticipatory comment the fact that war brought in its track epidemic disease which was usually more destructive of life than the sword or gunshot. The latter part of 1918 has seen the ravages of influenza, during which a toll of more than six million lives has been exacted, and many observers seem to be of the opinion that this pandemic is somehow associated with the war. Some of the views as to the causation may be dismissed as amusing. There is the bacon theory, for instance. The irrepressible Dr. Hadwen seizes the opportunity to invent a theory to fit the disbelief in the existence of microbes. We conceive it as a possible chemico-organic poisoning arising as an influenza miasma and disseminated by aerial connection via the Mediterranean from the region of the Dardanelles. He enumerates a few other agencies which may have contributed their effects. The *Inquirer* naturally leans to Dr. Bell, and gleefully inquires, "Is vaccination implicated?" The editor confesses to "some slight congestion of the brain and confusion of ideas" on the subject. "We know," says the *Inquirer*, "that millions of our soldiers have been vaccinated or inoculated many times during the war." It does not occur to the *Inquirer* that millions of our soldiers thus treated have not succumbed to influenza, whereas millions of civilians not so treated have been victims of the scourge. We are not surprised at the confusion of ideas just referred to. Dr. Bell and Dr. Hadwen are both pets with the antis. Dr. Bell says in the *National News* of November 5 that influenza is not influenza at all, but "breakdown fever," which he further says, "is microbic disease encouraged by the toxic condition of the bodies of the people it attacks." Now Dr. Hadwen asserts that there ain't no such thing as microbic disease. No wonder then that the confident believer in each of these "authorities" gets congestion of the brain when contemplating the divergent views.—*The Medical Officer*, January 18, 1919.

Dermatology in Brazil.—In the *Brazil-Medico* for November 23, 1918, is the report of an historical paper on this subject by Terra. Dermatology in Brazil began with the study of pian, which at the same time was confounded with syphilis. Without counting indigenous affections, white colonists and negro slaves brought their own ailments, including syphilis, yaws or pian, and lepra. A program published by the municipality of Rio in 1789 for proceeding against endemics in the metropolis mentions lepra by the term elephantiasis græcorum, while syphilis, which is not specified by name, may have been included with yaws under the name pian, as was the case two centuries before when the disease was called disreputable. Medical teaching did not begin until 1913, while the parent medical society was organized in 1829. The earlier graduation theses comprised many dermatological subjects. The first considerable monograph on the dermatoses of Brazil appeared in 1826 and shows that great confusion existed on the subject. In 1866 Wucherer who began the use of the microscope in Bahia made important discoveries in filariasis. At a later period Silva Lima did some pioneer work on the disease ainhum. In 1882 chairs in dermatology were founded in two Brazilian universities. Silva Araujo of Rio became famous as a teacher and clinician at the Policlinic, and within a short time pure empiricism had given way to scientific dermatology. An immense amount of original work has been accomplished in the domain of tropical skin diseases, and along with an abundance of material also known fully in temperate zones as syphilis and lupus, we see blastomycoses, sporotrichoses, leishmanioses, tropical phagedenic ulcer, granuloma venereum, frambesia, etc. The credit for accomplishing the cure of some of these apparently incurable maladies, like leishmaniosis and granuloma venereum, is given without stint to Vianna of the University of Sao Paulo.

The University of Strasbourg.—This institution having once more become French, a summary of its history is given by a contributor to the *Gazette des hôpitaux* in the issue for January 11. It was founded in 1621 as a continuation of the old Protestant gymnasium which goes back to 1538. At this period but three professors belonged to the medical faculty. When Alsace was ceded to France under Louis XIV the university became French, and so great was its prestige in the XVIII century that it even took precedence over the University of Paris. It seems to have been strictly a Protestant university until the reign of Louis XVI, when a few Catholic students and one Hebrew were admitted. In 1794, during the revolution, military and marine hospitals were established. A sanitary college was another new feature, and the faculty included numerous military surgeons. This new movement culminated in a separate Faculty of Medicine, which dates from 1802. Just before the Prussian war there were sixteen full professors and the same number of *agrégés*, and 511 medical students. This large number was due to the attendance of military pupils, over half of them being intended for army practice. The latter, however, were graduated at Val de Grace.

The university was germanized in 1871 and remained German until 1918—nearly half a century. In returning to French control the property which changes hands is valued at 23,000,000 marks, but little of which comes from German sources outside of Alsace. There is no intention of allowing the university to recede in any way from the standards set by Germany. But it will be French in ideals, just as for many years its ideals have been Teutonic. It will cease as a distributing point for German propaganda. It is to be hoped that American, British, Belgian and other students from the Allied nations will seek its doors for admission. The German university faculty comprised fifty-seven men, many of whom were Germans exclusive of Alsatians. There are only a few departments of modern medicine which are unrepresented. There will be no general upheaval, and for several years instruction will still be given in the German language. In 1871 the Germans sent their very best professors to take the reins, and France will be forced to take the same step.

SOME PRACTICAL POINTS IN THE DIAGNOSIS OF SYPHILIS OF THE NERVOUS SYSTEM.*

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL NEUROLOGY, COLUMBIA UNIVERSITY.

THE title of this paper, "Some Practical Points in the Diagnosis of Syphilis of the Nervous System," means that I want to call attention in an informal way to a few *practical* and *essential* points.

To diagnose a case of syphilis of the nervous system it is necessary first of all to recognize the fact that the patient is suffering from constitutional syphilis, and that, therefore, he may have any one of the many manifestations which constitutional syphilis gives. It is, therefore, imperative to make every possible clinical examination and every possible laboratory analysis. I make a routine measure in these cases, of *first* a history, *second* a clinical examination, *third* a laboratory analysis, and *fourth* an *x*-ray examination. I am not going to burden you with the details of each one of these, but rather emphasize the important points.

First.—The history in syphilis is not so important as one has been led to believe from textbooks and teaching. The man who has had syphilis does not wish to realize it, and often is unwilling to admit it. His mental attitude is that of one constantly looking for an excuse. He is constantly seeking for reasons to prove that, even if he has had syphilis, he has been properly treated, and therefore cured. I have met so many patients who say that they did not have a hard chancre, but one that was soft, and therefore not syphilitic. Again, I have seen so many patients, who, in telling their story, have omitted the infection of syphilis, and when it was finally brought up, the excuse was that the infection occurred twenty-five or thirty years ago, and therefore is no longer important. I have also treated many patients who did not mention the syphilitic infection, because, when it was brought up, they said that the infection occurred but was treated promptly and effectively, and cured, and so was of no possible importance in the present status of the case. Finally, there is a large class of patients who will deliberately deny that they have had a syphilitic infection. This is done to mislead the examiner, and because the patient is thoroughly convinced that syphilis is a bugbear and that the modern practitioner is on the alert for its symptoms. Therefore, if a syphilitic infection is admitted, the diagnosis of syphilis will be a foregone conclusion. All these point to the fact that the *history* in syphilis is of minor importance. Personally, in examining nervous cases, I think it is almost a futile question to ask a patient whether or not he has incurred a syphilitic infection. I believe that if he has had syphilis, you will probably acquire his confidence easier and more rapidly if you fail to ask him, and later prove it by the clinical and laboratory reports.

Secondly, the practical points in the *clinical examination* of the syphilitic are: (1) The condition of the pupils; (2) the condition of the reflexes; (3) the condition of the circulation.

Of these three, by far the most important is the condition of the pupil. In examining the pupil, look for three things—size, contour, and reaction to both light and accommodation. The *pin-point pupil* is much more suggestive than the dilated. Markedly unequal pupils are even more suggestive. The contour of the pupil is something which the neurologist looks for but which the general practitioner is prone to neglect. Of course, we know what contour means—the outline of the pupil. In the normal individual this should be smooth and even. Syphilis causes rough and unequal edges. Apparently the poison causes a breaking or bulging out of the line of the pupil. Perhaps the most important of all these three eye signs is that of the reflexes. A very sure, almost definite, sign of syphilis is the failure of the pupil to react to light. We all know this, but often fail to realize that before there is absolute failure in reaction to light, there occurs a partial failure, termed sluggishness. There may be every degree of pupil reaction, from the normal to a complete immobile pupil. The normal man has a pupil which reacts promptly; the man of neurotic temperament has a pupil which reacts in an unduly rapid way; the syphilitic has a pupil which reacts slowly. The sluggish pupil is almost as important as the immobile pupil. It precedes the immobile pupil, and is of great assistance in prophesying future trouble. I have known patients who have had for years pupils which were slow in their reaction to light and without any other physical signs, only to find that at the end of five or ten years they developed absent knee jerks and positive Wassermanns.

The condition of the tendon reflexes is of equal importance with that of the pupil. Changes in the reflexes do not, however, occur as early, nor progress as fast. The important reflex affected in syphilis is

*Read before the City Hospital Alumni Society, New York, Jan. 16, 1919.

the knee jerk. We must bear in mind not only that it may be absent, but also that it may be exaggerated, or that the two knee jerks may be unequal. Syphilis is a poison, and like alcohol or any other poison, it first stimulates, then depresses, and finally destroys. The arc of the knee jerk, when the poison first begins to affect it, over-acts, then weakens, and finally fails. During this process, whether syphilitic or alcoholic, one knee jerk may be more affected than the other.

The condition which an examination of the circulation reveals, is, to my mind, of equal importance with the one shown by the reflexes and with that of the pupil. The heart may be enlarged, there may be valvular lesions, especially aortic, and there may be a dilatation of the aorta, or even an aneurysm. There may be very high blood pressure, or there may be palpable thickening of the arteries. Marked attention should be paid to the condition of the circulation, and every possible effort made to determine its condition.

Thirdly, I want to call attention to the *laboratory analyses* which can and should be made in the examination of syphilis of the nervous system. They may be classified under two headings—those of the blood, and those of the spinal fluid. Of the two, undoubtedly the examination of the spinal fluid is the more important. As we learn more and more of syphilis of the nervous system, I think we shall become more and more convinced that a Wassermann test of the blood is less important and more misleading than it is valuable and suggestive. This seems a radical statement and at first rather difficult to comprehend. You will, however, agree with me when I say that I constantly see cases in which the blood Wassermann is negative, but the spinal fluid is positive, revealing a syphilitic infection. Again, I see many cases with a negative blood Wassermann which show a positive Wassermann a month later, or following antisyphilitic treatment. Another reason for considering the Wassermann of doubtful value is the fact that there is no standard in the laboratory for its preparation. Another reason is that the personal element enters into the report; and, again, that the test varies according to the amounts of blood examined. We must realize also that there are cases of syphilis of the nervous system in which there are not sufficient Wassermann producing bodies in the blood to cause a positive Wassermann to appear, whereas, there may be a sufficient number in the spinal fluid. Without any reflection on laboratory men, for none is intended, it is by no means unusual to find contradictory reports on the same patient from different laboratories. Another practical point to bear in mind is that certain drugs, when taken in large amounts, immediately before the Wassermann test on the blood is made, have the effect of reducing and nullifying this reaction. Thus, the alcoholic who has been taking large doses of alcohol for a few days previous to having his blood tested may very well send to the laboratory blood which is negative, whereas if he abstains for two weeks the same blood may return a positive Wassermann. There is no reason why this statement should not also apply to large doses of salvarsan; I believe it does. This is also the reason for the provocative test. The provocative test is one in which a negative blood Wassermann becomes positive after one dose of salvarsan. This means that the salvarsan, like every other poison, first stimulates then depresses. In this way it causes the Wassermann producing bodies to leave the corners and walls of the blood vessels and to be thrown into the general blood stream.

The examination of the spinal fluid is the one examination of prime importance in diagnosing syphilis. I consider that no examination of a nervous case is complete without a spinal fluid examination. It is by far more important than an *x*-ray, than an ophthalmoscopic, and even, to my mind, than a clinical examination. I think that there is no doubt now that the nervous system is affected by syphilis very early. We were formerly led to believe that the manifestations in the nervous system did not occur until ten or fifteen years after the initial lesion, but it is now beginning to be recognized that the nervous system becomes involved early—in the first few months—and that therefore the spinal fluid will reveal changes early. I am asking you to conceive of a case of syphilis of the nervous system as one of constitutional syphilis. Every case of syphilis has the nervous system affected and in some cases of syphilis the nervous system is much more affected than the other systems. These cases we call locomotor ataxia, paresis, and cerebrospinal syphilis. A common error which may occur in a laboratory report of syphilitic spinal fluid lies in the fact that the quantity of spinal fluid examined makes a difference in the tests. Small quantities of spinal fluid may not reveal a positive Wassermann, whereas larger quantities in the same individual may. Therefore it is necessary and important that we should ask the laboratory to indicate what amount of spinal fluid has been examined. The spinal fluid test is especially a quantitative test.

The cell count is not considered of so much importance as formerly. I do not believe that it is possible to indicate from the number of cells the form of nervous syphilis. All we can tell from a large cell count is that there is an inflammation, an irritation, an abnormal condition, in the spinal canal. This may be due to syphilis, mechanical disturbances, or a meningeal infection. In other words, anything which irritates or disturbs the spinal canal will cause nature to manufacture more cells. We know perfectly well that a spinal cord injection of almost anything, whether it be salvarsan, mercury, or saline solution, will stimulate the cells and cause an increased number. This means that the spinal membranes or meninges have been irritated. In reply to this irritation nature sends out an army of cells. We do know that the greater the irritation the greater the involvement of the meninges, the more intense is this meningitis, the larger the number of cells. Therefore, an acute involvement means hundreds and hundreds of cells and a subacute involvement means tens of cells. It is safe to say that a large cell count indicates a superficial or meningitic involvement and a small count of cells indicates an arterial or deep involvement.

A very important test is the colloidal gold. I will not go into the technique of this, but will simply call attention to the fact that no spinal fluid report should be considered complete without

a gold test. It is difficult to make, it requires a great deal of time, and the solution easily deteriorates. Therefore, the laboratory will not render it unless specifically asked to do so. The gold test shows a series of color changes in test tubes. These can be transferred to diagrams, and in this way charts can be made out. These charts present typical lines or curves in different diseases. They are given the names of paretic, tabetic, luetic, and meningitic curves. The gold test is the one of all most to be relied upon. I can, at this moment, cite two cases of epilepsy in which everything is normal —history, clinical examination, *x*-ray, and laboratory analyses, with the single exception of the colloidal gold curve. In these two cases, there is no history of syphilis, no indication of any Wassermann reaction in blood or spinal fluid, and no increase of cell count. There is, however, in each of these cases, a typical luetic curve. Each of these patients has typical convulsions, occurring with more or less frequency. One is a man in the "fifties" and the other a boy in the "teens." It seems fair to me to assume that with a typical luetic curve and a manifestation of convulsions, the cause of the condition is syphilis. Some of the laboratory men maintain that those cases in which the colloidal gold curve alone is positive later on show a positive Wassermann reaction in the blood and fluid. Whether this is true or not I cannot say.

When the cell count, the Wassermann, and the gold test are taken together, they form three arguments which I consider more valuable and more infallible than any other three—either the history, the clinical examination, or the *x*-ray pictures.

Fourthly, the *x*-ray is of value because it reveals the enlarged aorta the beginning aneurysm, the dilated heart, and occasionally, some specific condition in the head. It is the least important of the four factors which I have mentioned, but, taken in conjunction with the other three, will be of help.

A practical point of considerable interest, and also of some prognostic value, is the character, the severity, and the prevalence of the headache following the lumbar puncture. It has been my experience, and I think also that of many others, that the syphilitic cases are much less apt to have headache following a puncture than are the normal cases. This has become so well established a rule that it is almost possible to forecast the character of the puncture from the character of the reaction in the head following it.

There is nothing to do for these headaches, and very little to do before the puncture to prevent their occurrence. The only thing which I can suggest is to have these patients drink a great deal of water for twelve hours before the puncture. If this is done the headache will probably be diminished. This may be accounted for by the fact that the increased amount of water increases the amount of fluid in the human organism.

I might mention, in passing, that an excellent form of treatment for delirium tremens is the lumbar puncture. Those cases in which the mental symptoms are pronounced, and in which the delirium is very great, will be aided by the removal of 30 or 40 c.c. of spinal fluid.

Finally, the one important point in diagnosing syphilis of the nervous system is to get as much data as possible and then to correlate it properly. Weigh the history with the clinical findings, with the laboratory report, and the *x*-ray pictures. Do not stop at any one of the four, nor at any three of the four. If you must place emphasis on one more than any other, let it be on the laboratory report of the spinal fluid. If I suspected a syphilitic infection, and was told that I could have only one of these four methods to prove or disprove its presence, I would ask for the spinal fluid examination, and after this the Wassermann test and the gold test. If these were positive, and everything else was negative, I would know that the case was one of not only syphilis of the nervous system, but also constitutional syphilis.

41 East Sixty-third Street.

A THEORY OF ASTHMA AS CONFIRMED BY NEARLY FOUR HUNDRED CASES, SUCCESSFULLY TREATED.

By MARK I. KNAPP, M.D., LL.M.,

NEW YORK.

One of the hardest propositions one is up against is, when he differs from the accepted views and attempts to remove, what to him seems to be, an erroneous assumption. When he has concrete facts with which he can convince his hearers his road is easy enough. But, when instead he is to face a profession, justly prejudiced against any innovation and he has to appeal only to abstract thinking and reasoning, his task is certainly not a very enviable one. It was easy enough to prove to the world, and that instantly, that there existed certain rays which enable us to look through dense matter. The rays were there, the matter was there, and all one had to do was to look. But when we have been taught for centuries past that asthma is a spasm of the bronchial tubes, and when I now attempt to disprove this as a most erroneous and fallacious theory which has never been proved, I beg that the reader follow my remarks most closely. I have no specially constructed physical instruments to prove my contention. All I offer is reasoning. I shall attempt to reason out that the view of the profession, that asthma is due to a spasm of the bronchial tubes, not only has been the merest speculation, not only has never been proved, but from the very nature of it never can be proved.

In this monograph we are concerned with the subject of asthma, and the first question is, is the present teaching of asthma based upon actual scientifically proved facts, or are such teachings merely a repetition of views held for ages, the validity of which no one thought of challenging or dared not challenge. What are we taught is the immediate cause of asthma? For an answer the books give us that the asthmatic spell is due to a spasm of the bronchial tubes. This teaching I challenge. What proof is there or has there been given or can be given that a spasm of the bronchial tubes is present? Proof, of necessity, can be only of two kinds, the direct proof and the indirect proof. We naturally prefer the direct proof. Have we any direct proof of the existence of a spasm of the bronchial

tubes? I have failed to discover such. Moreover, such proof is impossible of production. A spasm is a manifestation of a vital activity, that is, a manifestation which is possible only during life. There is no spasm of visceral structures after life has departed. Therefore, a positive demonstration of a spasm of the bronchial tubes at an autopsy, could such be performed on an asthmatic patient while in an asthmatic spasm, is absolutely impossible. Nor is it known that an asthmatic ever submitted to the opening of his chest during an attack, so that the presence of a spasm of the bronchial tubes could be definitely proved. Neither in the past nor at present has an absolute, direct proof of a bronchial spasm been produced, nor can such direct proof be produced. We are therefore compelled to analyze critically the adequacy of the indirect proofs which have been given us and from which we are to reason out the presence of a bronchial spasm. Here again we are surprised by the paucity of arguments; in fact, there are no arguments advanced. We merely find the dogmatic assertion that the asthmatic attack is due to a bronchial spasm. No substantiation of such an assumption seemed necessary. Our forefathers so believed it and so must we believe.

Let us now reflect. Can we assume the presence of a bronchial spasm without at the same time denying well established self-apparent scientific and clinical facts? A spasm means a contraction. A spasm of the bronchial tubes means a contraction of the bronchial tubes and a contraction means a diminution of the lumen of the bronchial tubes. Therefore, a spasm of the bronchial tubes means a contraction of the bronchial tubes and a diminution of their lumen, and when there is a diminution of the lumen there must necessarily be a lessened quantity of air getting into the air cells. The necessary consequence of this must be a lack of distention of the air cells. This, again, is equivalent to a lack of expansion of the lungs *in toto*. But the clinical evidence of this insufficient distention of the lungs is retraction of the intercostal spaces and not their distention. The clinical evidence of insufficient inflation of the air cells of the lungs is not a fullness of the chest wall, but the very opposite; the chest wall is diminished in its various diameters. This reasoning is excellently exemplified by the clinical phenomena which accompany a diminution of the lumen of the larynx, be this due to spasm of the larynx, or its inflammation with membrane formation, or to some growth within the larynx or surrounding it, and pressing upon it. Retraction of the chest, retraction of the intercostal spaces, retraction of the supraclavicular fossæ are the clinical evidence of a stenotic condition of the larynx. In marked contrast to this is the clinical picture we behold during an attack of asthma. Not only is there no evidence of any retraction of the chest and of the intercostal spaces, but one sees the very contrary picture. The chest is distended, the intercostal spaces bulge out, the supraclavicular fossæ are full. If the causal relationship between stenosis of the larynx and the retraction of the chest be firmly established; if we be sure that the one conditions the other, then the deduction is patent that whenever we find a general retracted condition of the costal interspaces, there must be an obstruction to the filling up of the lungs with air. And, conversely, whenever we are sure that there is an obstruction to the filling up of the lungs with air, there must be external evidence thereof in the retraction of the chest. Therefore, it is preposterous to maintain that there is an obstruction to the intake of air, that there is an impediment to the filling up of the air cells, which is the necessary corollary of a spasm of the bronchi, when the chest shows not only no retraction, but the very contrary, when it does show fullness, distention. So much we can learn from the mere inspection of the chest during an asthmatic attack. But we have additional evidence of the fallacy of our present conception of the cause of the asthmatic attack. If it be true, that the asthmatic attack is due to spasm of the bronchial tubes, then we must assume, as already stated, an obstruction to the taking in of air. This could be evidenced only, as in the stenotic condition of the larynx, by labored inspiration. Again, this is not the fact. All who are familiar with an asthmatic paroxysm know, that the patient's trouble is not with the inspiration, but with the expiration. The inspiration takes place freely enough. It is the expiration which is causing the agony. During the asthmatic paroxysm we note the short and absolutely free inspiration, followed by the very labored expiration, during which the patient bends forward and, as a rule, gets hold of some piece of furniture against which he braces. He uses that to bear down upon as, similarly, does the parturient woman, and in both instances the additional force, gained by such intuitive effort, is used for the purpose of expulsion—the air in the one case, and the fetus in the other. Auscultation offers additional proof of the mistake in which we were reared. Asthmatic wheezing is heard in the much prolonged expiration, while the inspiration is about normal.

Believing that the foregoing remarks will cause the earnest reader, if not to change his views at once, at least to begin to think over the question elaborated above, I will now proceed to the discussion of another fallacy—our erroneous interpretation of the act of coughing. From time immemorial the act of coughing has been associated with some pathological condition of the respiratory tract. So ingrained is this view in us, that I feel that, even the slightest allusion to the questioning of its correctness may cause violent resentment in the reader. Of course, everyone admits and knows, that causes other than pulmonary or bronchial may initiate a spell of coughing. We know of a stomach cough, a cough produced by some solid particle lodging somewhere in the pharynx or thereabouts and of some other coughs. But, in the main, we associate cough with "catching cold." If cough is produced by various agencies, as we know it is, then all such various agencies must have some one factor in common which elicits the cough. Since to produce coughing we must have an irritating agency and an irritated spot, and since we know that the various agencies which cause coughing are of entirely different physical construction, the alternative left us is, that all agencies irritate the same spot. Moreover, since we know that the coughing may be

caused by matter coming from without and by matters coming from the lungs or the stomach, the irritated spot must be located there, where both external and internal irritants can reach. Are there many anatomical spots which may cause the cough, or is there only one? In other words, is the cough producing area limited in extent, must internal and external causes concentrate on one spot, or is there a large surface which will respond by coughing to an irritation? I shall attempt to prove that all irritants, whether they come from without the body or from within it, do concentrate their action on one spot, that it is only one spot which is irritated and which, when irritated, causes coughing. If I succeed in this the reader will understand the cause of the asthmatic paroxysm. Inasmuch as I cannot prove my contention by affirmative evidence, I shall have to resort to reasoning by exclusion. My daily and routine practice with the stomach tube has proved to me in innumerable instances, that the patient gets a violent fit of coughing when the stomach tube reaches the pharynx. A hair lodged on the pharyngeal wall will cause coughing, which will continue until the hair is removed. The nose and throat specialist is well acquainted with the coughing spells he causes by his applications to the pharynx. These illustrations will suffice to prove that an irritation of the pharynx will cause coughing.

In the following illustrations it is evident that the cough did not come from the lungs or bronchi. A patient came to me for his asthma. His history was, that he got up every morning with a severe spell of coughing followed by vomiting. The examination proved that he had a sacculated esophagus, where the food remained over night and began to decompose and that the irritation proceeding from the decomposing food brought about the coughing; the coughing stopped with the emptying of the sac. This diagnosis was subsequently confirmed by the *x*-ray. In another case it was the great distention of the stomach, due to decomposing food, which caused incessant coughing. A colleague who was in attendance on this patient insisted on the administration of opiates, which however failed to stop the coughing. Immediately after the washing of the stomach the cough stopped. Against my advice my friend insisted on giving food to the patient, which invariably caused great distention of the stomach with the accompanying incessant cough and which cough instantly stopped after lavage.

Another illustration: A young man came to me with the history of having coughed for some three and a half years. He consulted various physicians without avail and was finally told that, most likely, his cough was caused by some stomach trouble and, therefore, he came to consult me. I treated his digestive disorder and his cough stopped definitely and finally after the sixth day. Was the stomach the seat of the cough, or, as in the first illustration, was the esophageal sac the seat of the cough? If these structures were the seat of the cough, then invariably whenever there would be irritation of these structures cough would have to result. But we know that this is not the case; irritation of these parts does not necessarily cause coughing. On the other hand, irritating, volatile substances from below the pharynx are forced to ascend and in this way reach the same spot, which is reached when the irritating substances come from without the body, that is, in both instances the pharynx is reached. Can we focus upon the pharynx irritations emanating from within the lungs? That it is not every pathological lesion of the lungs which evokes coughing is sufficiently attested clinically. Only such processes are accompanied by cough which are undergoing active chemical changes, such as mucus and pus. These decompose or otherwise undergo chemical changes, one phase of which is the production of volatile irritating substances which reach the pharynx and cause the coughing. There cannot be any question that the irritation of the pharynx does cause coughing. Would it make any difference whether the pharynx is intentionally irritated by instrumentation or applications, or whether it is involuntarily irritated by some noxious agency issuing from some neighboring structure or some neighboring organ, or even from some distant organ with which the pharynx may directly communicate? Assuming my proposition to be correct, we can understand how pathological conditions remotely situated as, for instance, in the intestines, may produce coughing when the volatile substances finally reach the pharynx. Of course, matters of an irritating nature, whether solid or gaseous or liquid, if they reach the pharynx through eructation or vomiting may also cause coughing. While the cough is called forth by irritating matter the object of the cough is to remove the offending substance. This is effected by what I may call the pneumatic piston. This is created by the air column which is shut in by the closed pharynx and the closed glottis. This is axiomatic, that the irritation of the mucosa of any muscular structure causes the contraction of such muscle. And so the irritation of the mucosa of the pharyngeal vault causes the responsive contraction of the regional muscles, especially of the middle and superior pharyngeal constrictors and of the geniohyoglossus. The result of the combined action of these muscles is to draw the root of the tongue backward and downward and the pharyngeal muscles forward and downward. The conjoint action of all these muscles seals the pharyngeal opening and also seals the larynx, which by the action of the geniohyoglossus is brought forward and upward beneath the tongue, the tongue effectively closing the larynx. Preceding the action of these muscles the patient takes a deep breath and the escape of the inspired air is prevented by the violent contraction of the muscles, just mentioned. Now the abdominal muscles and the diaphragm are violently contracted, exerting pressure upon the air, inclosed and shut in in the bronchial tubes, trachea, and esophagus. The air column so inclosed and compressed acts like a piston in its attempt to force in front of it the irritating matter. In the case of the irritating matter in the esophagus the pneumatic piston is assisted by peristalsis and glandular secretion and gradually the offensive matter is loosened and expelled. Similarly, we proceed with expelling offensive matter from the nose. A deep breath is taken and the nostrils are occluded with our fingers; the inclosed air under pressure acts like a piston and the irritant is expelled from the nose.

After these preliminary remarks I wish to carry the reader through the successive stages of my accidental discovery of the cause and the cure of asthma. I, surely, never had any design to discover anything about asthma; I knew asthma was incurable, although a long list of remedies is given for the relief of the asthmatic spasm. But it happened in the following way: A woman about 43 years of age came to consult me some 14 or 15 years ago; I was recommended to her for her stomach trouble. She was in great dsypnea when I saw her. "Doctor," she said, "I came to find out whether my digestion could be improved somewhat, and, by the way, I have suffered from asthma for a number of years and doctor J. is treating me for it; never mind my asthma, I shall be happy if you can make my digestion better." I felt very happy that she relieved me of any responsibility regarding her asthma and proceeded to examine her. The result of the examination was that I found that she suffered from insufficientia pylori. This disease I described for the first time in the *Philadelphia Medical Journal* May 24, 1902, and since then I have contributed a number of articles on this disease in the various journals. As insufficientia pylori I have described the condition of the weakening of the pylorus, which, if unchecked, results in complete relaxation of the pyloric sphincter; insufficientia pylori being the natural sequel of the long-continued pyloritis, *i.e.* spastic contraction of the pylorus. In insufficientia pylori the ingested food does not remain in the stomach, but passes on into the duodenum without having previously been acted on by the gastric juices. This latter happens only when complete relaxation of the sphincter has set in. Having found that the patient did suffer from insufficiency of the pylorus I assured her that, as far as the stomach trouble was concerned, I could promise her recovery. The treatment required daily administrations. Some ten days, after treatment was begun, the patient told me that she felt not only better in her stomach, but that also her asthma was better. I certainly was pleased to know that she was getting better, but I paid little attention to her remark about the asthma. A mere accident, I thought, and so I dismissed it from my mind. After a few weeks the patient surprised me with the information that her asthma was entirely gone. However, I thought of it in no other light than that the asthma cure was a mere accident.

Some time later another patient came with insufficientia pylori complicated by asthma and in a few weeks both the insufficiency and the asthma were cured. Another accident, I thought. In the course of time another patient came in whom the insufficiency of the pylorus was complicated by asthma. And again cure of both resulted in a few weeks. This third and consecutive accident began to puzzle me, but even now I believed it a mere accident and that it was, purely, good luck of mine. I resolved to take advantage of my apparent good luck and thought that, when the next case of asthma came, I would cautiously hold out the hope for a possible cure of the asthma. I had nothing to lose, since all my patients came to consult me only for their stomach trouble and, if I had not succeeded in curing the asthma—well they did not come to me for an asthma cure. I was therefore quite safe. The fourth asthma case came and I acted as I had resolved. Again the asthma was cured. I now began to think seriously over the matter. What was it that happened? My diagnosis of insufficiency of the pylorus was absolutely correct. So was also the fact that all four patients had asthma and that all four patients were cured of their long standing asthma. Since the cure of the asthma was a fact, I had to conclude that there must be some sort of a connection between it and the insufficiency of the pylorus. What was the connection? In pondering over this problem, the following theory appealed to me as the most plausible.

In insufficientia pylori, according to the degree of the insufficiency, the food leaves the stomach either not at all digested or only partly so. The books teach us that there is a vicarious action and that the food which is not digested by the stomach will be vicariously digested in the intestine. But such an hypothesis cannot be admitted. The stomach digestion is acid and the intestinal digestion is alkaline. To assume that the food, which merely represents a chemical compound, can be equally digested by an acid and an alkali, that is, that the same identical chemical compound will be acted on and react equally with an acid and alkali, shows lack of knowledge of chemical principles. If there is such a thing as vicarious action elsewhere, it is not in the gastrointestinal tract. Therefore, the food which must be digested by an acid and is not so digested, will and does undergo chemical changes in the intestine, which changes do not work for the health of the individual. In my experience on hundreds of cases I have found that insufficiency of the pylorus causes excessive acidity within the intestines and, very often, irritating gases. Let us first discuss the question of excessive gas formation in the intestines. We must bear in mind that gas formation is a natural process which accompanies digestion. It is the overproduction of gases which becomes pathological. I dare say that every reader has experienced the sensation of overdistention of the intestines with gases. Not only do we feel uncomfortable, but very often we have to loosen our clothing because of the overdistention of the intestines. If there is sufficient pressure outwardly upon the abdominal wall which compels us to open our clothing, we can safely assume that there is like pressure in all other directions, wherever the intestines are lodged, that is, all over in the abdominal cavity. This gas pressure is at times so great that it dislodges even the liver and forces it upward. This condition has been seen many times by the surgeon, who has found the liver being pushed into the thoracic cavity because of the gas distention of the intestine. We are therefore fully justified in asserting that, whenever there is great distention of the abdominal wall by gases within the intestine, there is like great pressure upward against the diaphragm, and, therefore, against the lungs. Thus, the normal respiratory excursions of the lungs are very much interfered with; the lungs are prevented from fully expanding. I am sure that the reader is familiar with the frequent history of indigestion, fullness in the stomach and

painful breathing, the pain being located in the left side, which is most often, and unfortunately, diagnosed as a 'touch" of pleurisy. As the normal rate of respiration is 18 times a minute, it is 18 times in a minute that the lungs are prevented from performing their natural function. This interference with the respiratory expansion of the lungs continues not for a minute, nor for an hour, nor for a week, nor for a month, but for months and years. Can the physician admit that such interference with the respiratory expansions will go on for such length of time without impressing the lungs pathologically? Must we not, under such circumstances, expect that, sooner or later, the lungs will give manifestations of a pathological condition? And the pathological condition of the lungs which manifests itself here we have named asthma. Having reached this reasoning I could clearly understand how my four successive cases of asthma were cured. With the cessation of the excessive gas formation the lungs were no more crowded and could therefore fully expand. This chronic overdistention of the intestines constitutes the asthmatic constitution. The asthmatic attack is ordinarily called forth by the organacidia enterica, the excessive acidity of the intestines, this acidity being caused by irritating, volatile organic acids, which are forced up through the open pylorus and cardia into the esophagus and pharynx when its irritation initiates the spasm and cough. But, given the asthmatic condition, other irritants may precipitate the asthmatic paroxysm, whether the irritants be of a solid nature, such as dust, flour, hairs from fur, pollens, or whether the irritant be of gaseous nature. The irritants just cited do not produce asthma unless there is underlying an asthmatic constitution. The more I thought of this foregoing theory as explanatory of the cause of asthma the more likely it appeared to me, and my success in nearly four hundred cases confirmed the correctness of this theory.

Etiology.—The foregoing sufficiently sets forth my view as to the etiology of asthma. A few remarks on the erroneousness of the assumed causes, as at present being taught, may be in place. Asthma appears either in winter or in summer. Some patients suffer only in the winter and others only in summer. The fact that it comes in summer excludes the correctness of the hypothesis that asthma is due to the inhalation of cold air, a view expressed by some authors. That asthma comes in the winter, and this is in most of the cases, will at once exclude the inhalations of pollens or of other plant substances from playing any rôle in the etiology of the disease. Neither seashore, nor inland, nor mountain, nor valley is exempt; asthma is found everywhere and therefore these cannot be looked upon as inducing asthma. Cardiac and renal disease is often alleged as the excitor of asthma. But I have had these cases in my practice; the asthma got better and the cardiac or renal trouble remained. Nor is age a determining factor; my youngest patient was six months old and my oldest 84 years. So far I have been unable to see that one or the other sex is more prone to asthma; both sexes suffer alike. That asthma is not due to nervousness, the following history will serve as an illustration. The six months old baby, which I just mentioned, was brought to me by its mother, to whom I had been recommended by a cured asthma patient. I treated the mother and the baby got well, and now, over four years after, I heard from a patient, whom the child's mother sent me, that the child is now a healthy little girl and has not had asthma since I cured the mother; the mother nursed the baby.

We constantly hear of some pathological nasal condition being the cause of asthma. This is not borne out by my experience. Surely one-third of my patients have come to me after they had had one or more operations on the nose; the fact that they came to me proves that the nasal trouble was not responsible for the asthma.

Symptoms.—In the first years of the disease the asthmatic attacks come either in winter or summer. But after the persistence of the asthma for several years the suffering continues, with greater or lesser severity, throughout the year, although there may be some slight intermissions for short periods.

The asthmatic attacks are ushered in mostly very suddenly. But occasionally there are premonitory symptoms, well known to the patient himself. The usual run of an attack is as follows: Towards 3 or 4 o'clock in the morning, and while the patient is still asleep, the respiration becomes labored, accompanied by wheezing. This naturally is observed not by the patient himself, but by his family. Suddenly he wakes, sits up in bed and assumes a posture most favorable for forced respiration. The thighs are drawn up towards the abdomen and the legs flexed upon the thighs. The body flexes forward to meet the thighs. The forearms are flexed upon the arms and the elbows rest upon the knees, the hands supporting the chin. All the auxiliary muscles of respiration are brought into play. Soon the mucous membranes of the lips become livid and the patient's body is bathed in cold perspiration. The mouth is open and the chin drops; the eyes bulge out, he gasps and labors for air. Suddenly he jumps out of bed and runs to the window, which he tears open. In the severer cases the patient is unable to stay in bed and for weeks and months he gets his sleep sitting in a chair, never going to bed at all. When he is seized with a paroxysm while sleeping in his chair, the patient jumps up and gets hold of some piece of furniture against which he braces with body bent forward and head thrown back. No matter how many attacks the patient has gone through, he always thinks this present attack will end his life. The duration of the paroxysm is not always the same and may last from half an hour to several hours. At the end of the paroxysm gas and mucous are expelled from the mouth.

What is the explanation for the paroxysm; what causes it? Taking note first of the time at which the paroxysms usually are initiated, we see that they occur at a time when the ingested food has left the stomach and has already reached the intestine, where the particular chemical changes take place which create the irritating gases. The attack occurs from six to eight hours after the last meal. The esophagus and pharynx, already in a pathological condition, receive now additional irritation. This irritation the patient attempts to re-

move by the only means at his disposal, by coughing. But also the peristalsis of the esophagus comes into play. The pharyngeal and glossal muscles contract, thus closing the passage of air and gas from the esophagus and the trachea, thus forming the pneumatic piston, and the concussions of this pneumatic piston against the occlusion begin by the act of coughing. Meanwhile the irritant in the intestine continues to be generated and to be forced up so that it augments the irritation which provokes greater coughing concussion. To each inspiration there is a series of cough concussions in rapid succession, and if the irritant is solid it will be removed in a short time, unless it is imbedded in the structures. But if the irritant is of a chemical nature, not one introduced from without, but one constantly being formed and reformed in the intestines, the irritation will naturally continue, until the formation of such irritating volatile substances has ceased, or until the chemical irritants have become attenuated or neutralized. The peristaltic action of the esophagus not only milks the glands but stimulates their secretions, which help to counteract the chemical irritants. As full an inspiration is taken as is possible, and the air cells become fully distended. The abdominal muscles and the diaphragm are violently, rapidly, and in a concussive manner contracted, the concussions being exerted against the fully inflated air vesicles. The longer the irritation continues, the greater are the efforts to overcome the irritation, and, involuntarily, the aid of the auxiliary muscles of expiration is peremptorily requisitioned. But as the irritation lasts for several hours and the muscular contractions of the auxiliary muscles of respiration gradually give way, their force against the distended air vesicles diminishes. Thus the distended walls of the air vesicles are put under greater strain, and in the course of time lose much, if not all, of their elasticity; the air vesicles are or remain distended. Under normal conditions the air cells and the bronchioles are adapted in size to each other and produce the sound which we call vesicular breathing. Any modification of this relation between the lumen of the bronchiole and of the vesicle will necessarily have an effect upon the pitch of the sound. When the air vesicle is distended, the lumen of the bronchiole, by comparison, is now less than before, the pitch of the sound is relatively raised, and the quality of the tone is changed to musical. That the distention of the air vesicles is not hypothetical but an actual fact is seen in the enlargement of the chest and in the bulging out of the intercostal spaces. It is true that the lumen of the bronchial tubes is inadequate during an asthmatic attack. But this diminution is not caused by a spasm of the bronchial tubes, but, because of the distention of the vesicles the caliber of the bronchial tubes becomes relatively smaller. When, after a variable length of time, the irritation has finally been overcome the spasm ceases and the pent-up gases are expelled together with some mucus.

Between the attacks the patient feels more or less comfortable, but he is always careful of any exertion; he cannot climb stairs and cannot walk any distances. Palpitation of the heart, especially on climbing or going up stairs is a very frequent symptom. The patient complains of belching, fulness in the region of the stomach, and fulness in the abdomen. Deficiency of teeth is the rule, although there are many exceptions. I mention this because I have already, in my first monograph on insufficientia pylori, called attention to this state as being intimately connected with the causation of insufficiency of the pylorus. Pain in the precordial space, of which very many patients complain, may unquestionably be occasionally due to actual heart trouble. But, I found heart disease a very rare complication in my practice. I believe the tendency to be, that the physician will give the patient the benefit of the doubt, whenever the latter complains constantly of pain in the region of the heart, and call it heart disease even when there are no physical signs whatsoever to permit of such a diagnosis. This I have seen innumerable times, and the physician then treats a non-existent heart disease with very unpleasant results as a consequence. Based upon my experience in numbers of instances, I believe that the physician should think of the heart last, whenever fluttering, palpitation, and pain in the region of the heart are complained of, and never should the physician make the diagnosis of heart trouble, unless there are absolute physical signs present for the diagnosis. The reason for these constant errors is the following: There is gas accumulation in the stomach, duodenum, and the jejunum. The gas presses upward against the diaphragm and through it against the heart. The normal, unconscious heart action is interfered with by the encroachment of the distended intestines upon the excursions of the heart. The fact present is, that the heart is beating against a resistant body and the rhythmical shocks of the heart against the gas distended body calls forth the sensation of pain. One can easily ascertain this fact by sharply striking, even if very lightly, upon a distended portion of his own intestine or upon a patient's intestine; pain will be elicited. Besides this there is the distention of the fundus of the stomach against the ribs and also the pressure of the heart forward against the ribs and the consequent compression of the coronary artery. All these elements enter into the causation of uneasiness and pain in the region of the heart and also of the painful breathing of which the patients complain.

The appetite varies. The usual history is that they have appetite, except during the attack. This depends upon the acid condition of the intestine. If there is excessive acidity, there is appetite, for the acidity causes the contractions which cause hunger. But, as during the attacks there is gas distention, there is absence of appetite so long as there is distention. Those who are interested in the question of the appetite I would refer to my articles: "Organacidia gastrica" (MEDICAL RECORD, Sept. 6, 1902), "Additional Notes on Organacidia Gastrica" (*Phila. Med. Jour.*, March 28, 1903), and "The Nature and Cause of Appetite, Hunger, and Anorexia" (*Amer. Medicine*, Aug. 26, 1905). These articles where I have described the nature and the cause of appetite have been made the cause of investigation by several experimental physiologists, prominently amongst whom is W. B. Cannon, why fully confirmed my deductions. Contractions of the stomach and duodenum up to a certain degree give the

sensation of hunger. Distention of these parts, being the opposite of contraction, also produces the opposite sensation from hunger, that is, distention has as consequence loss of appetite. And since during the asthmatic attacks there is distention of the stomach and intestine, it follows that loss of appetite must be the consequence. Constipation is the most frequent symptom.

Diagnosis.—Very often the patient comes to consult about asthma, and the chest examination fails to reveal anything abnormal. The physician should then be on his guard. On auscultation we may not hear any of the well-known rales, yet the patient may be an asthmatic; the patient simply came at a time when his chest showed no evidence of asthma. Under such circumstances it is best to explain the true facts and urge the patient to return after a short while. If necessary, one may give him some placebo until he comes again. When a patient comes to the physician complaining of asthma, it is the safer rule to treat him on the theory that he has asthma, even if the characteristic auscultatory signs are, for the time being, absent. Ordinarily the diagnosis of asthma can be made when the patient is in an adjoining room, without even seeing him, so characteristic is the rhythm of the breathing. It is the short, free inspiration followed by the labored and prolonged expiration which is associated with the wheezing. The only other disease which gives the same rhythm is pneumonia. But in pneumonia the respirations are increased in number. Not so in asthma; also, in asthma the expiration is much deeper and more prolonged. Then, although not always, the wheezing can be heard from a distance. However, every patient must be stripped and examined. But not always can we hear the wheezzing when the patient is erect, sitting or standing. The patient is then put in the dorsal position, and if auscultation in this position should not bring out the wheezing, the examining chair should be inclined to an angle of about 40 degrees, so that the head of the patient comes down and the feet up. This inclined position is most excellent not only for the examination of the heart and lungs, but especially for the palpation of the abdominal organs. In this posture the wheezing will be heard when it could not be heard in the other positions. It is heard in expiration. One must learn to distinguish and to recognize a coexistent bronchitis. The physician will always elicit the history of a digestive disturbance, and, upon inspection of the abdomen, the gastric region will show its evidence. Over this region we may see a wavy tremulation, indicating the presence of gas, and which is being produced by the propagation of the pulsations of the abdominal aorta. Of course, the gastric condition must not be guessed at; the diagnosis must be made, after a test meal examination. The examination of the test meal in insufficientia pylori is described in my article in the *Philadelphia Med. Journ.* of May 24, 1902, and the ordinary test meal examination, in the article on organacidia gastrica in the MEDICAL RECORD for September 6, 1902.

Prognosis.—Contrary to what we have been taught, the prognosis is excellent. It is more than this. The affiicted begin to feel better almost the very day the proper treatment is instituted. Usually within 36 to 48 hours the difficulty with breathing begins to abate and after months of sleeping in the chair the patient can now go to bed. This alone makes him feel very happy. The attacks begin to lessen in severity and in frequency. But the patient requires a great deal of encouragement. He begins to feel better and believes that the attacks must stop right then and there, and just as soon as an attack comes again he is discouraged. Notwithstanding the fact that each patient is told that he must expect more attacks after the treatment has been begun, he, nevertheless, loses heart with each succeeding attack. We must then learn to exercise extreme patience and forbearance and must, in most positive terms, reassure our patients of success. Very often they will report progressive improvement the first eight or ten days and then begin to complain. My stereotyped question always is, what did you eat? The patient, usually will first deny, but after a while will admit his digression from the dietary rules. As an illustration I will cite the following two cases: A man 53 was being treated with excellent result the first ten days. Then he began to complain of not feeling well and of slight attacks. He denied that he varied from the rules as laid down. One day after this patient had left, the patient following him told me that in the waiting room this man had said that he was absolutely disregarding my advice as to the diet and that he ate and drank as he pleased. The following day I gave the disobedient patient a severe lecture, and he promised to mind me, which he did and he then got well. The other illustration is of an old lady, 71, who had suffered from asthma for very many years. She soon enough began to feel well, but after a while she began to complain again. As in all other cases she at first denied infringing upon the dietary rules, but, conscience stricken, she subsequently admitted her sins. So she went on for quite a while, but, finding that she continued to disobey, I finally gave her up. This seemed to have had a salutary effect upon her. She gave up her experimenting with forbidden food and I infer that she is well from the fact that she has repeatedly sent me patients. The treatment takes from three to four months, and after this the patient must continue on a moderately restricted diet for a period of about a year or so.

The question always comes up whether asthma, once cured, will remain cured. Asthma will remain cured, if the patient will abstain from again abusing his stomach. If deliberately and with utter disregard of injunctions he eats and drinks things which he should not, he will always have to pay the penalty. The advantage which the patient has is that he knows his enemy, he knows what he should not take and he must not take it. Asthma is just as curable as every other curable disease; the permanency of the cure depends upon the patient himself. The patient must be impressed with the knowledge that after he has been cured it becomes a question of his diet, which is not at all very restricted. Asthma originally developed because of the faulty diet, which caused the gastrointestinal condition, and, as often as the patient wishes to revert to his old bad habits, he will have to suffer for it. On an average the cure requires treatment for about four months.

Treatment.—For the successful treatment of

asthma we must take cognizance of all accompanying complications. Where the teeth are deficient, absent, decayed, or otherwise requïre care, such care must be given them. Nasal obstructions, adenoids, antrum or sinus disease must be overcome. To use an illustration: Supposing we find big cracks appearing in a wall and some pieces of ceiling falling down and we call the architect, whose opinion it is, that the foundation of the house requires repairs and that such repairs to the foundation are made. These stop the house from going to final collapse. But the mere attention to the foundation will not at the same time cure the cracks in the wall or the fallen-down ceiling. The cracks and the ceiling will also have to be repaired to make the house perfect. The mere curing of the asthma will not cure the other complicating conditions.

With almost no exceptions, all patients suffer from insufficientia pylori, the degree of which must be ascertained. I will give here a very brief summary of insufficiency of the pylorus. The patient is given a full and mixed meal the night before the examination and is told not to eat or drink anything after this meal until the following morning, and to come to the physician on an empty stomach. The patient must be specifically warned not to eat or drink anything after this meal until he comes for the examination. My routine is to give the patient the first examination with the stomach tube on the fasting stomach, in order to ascertain whether or not the stomach is empty, and if found not empty what is the nature of the contents. Next the patient is given 35 grams of plain white bread and 300 c.c. of water, after which he waits in the office of the physician one hour, during which he is not permitted any exercise. After one hour the stomach is aspirated. If no contents are found, the diagnosis is insufficiency of the pylorus. Its degree is ascertained, by giving the patient repeated test meals, one day after the other, but aspirating each day one-quarter of an hour earlier. The object of this is to find out how soon the stomach is empty of its contents so that the patient may get the medicine in proper time. The setting in of the insufficiency is recognized, when only a very small quantity of chyme is aspirated which has a spongy appearance. The treatment of insufficiency of the pylorus is alkaline, not acid. That is, taking cognizance of the fact that the food does not remain in the stomach, but passes into the intestine too soon, our object must be to increase the efficiency of the intestinal digestion, which requires alkalies. This advice is based upon experience. I had given acids first, but after a thorough trial got no results. I then determined to experiment with the alkalies, and this proved successful. Most often I use the sodium, magnesium, and calcium salts; but the potassium and ammonium salts are also very frequently of great benefit. Which particular salt is to be used and in what combinations is largely a matter of experience. The plain rhubarb and soda mixture with magnesium and the salicylate of sodium is a very good combination. In addition, cascara, nux vomica, strychnine, and the mydriatics may have to be employed. For the constipation which is almost invariably present I have found of excellent service the following combination: Podophyllin and aloin, each one-quarter grain, phenolphthalein one to one and a half grains, and atropine one hundred and twentieth of a grain, to be made into pills; one pill every night. In many cases the addition of colchicum to the alkalies proves very beneficial. Of the iodides I prefer the ammonium. Of the saturated solution of ammonium iodide we begin with a few drops and gradually increase the dose. For adrenalin I have no great admiration; I have long ago given it up in routine treatment. The general rule should be to use as few drugs as possible. Morphine I never use in the treatment of asthma, alhough I do use it in the treatment of an intercurrent attack of bronchitis.

Our chief reliance must be in the diet. Unfortunately no set rule can be given; what may be meat in one case may prove poison in the other. Each case must be studied by itself. As a general rule vegetables are not tolerated; but neither are all kinds of meat. Whilst this seems to be the rule, there are many exceptions. Many patients get along splendidly on one kind of vegetable or on one kind of meat and others get acute attacks after the same kind of diet. Our experience is our only guide. We must never lose sight of the fact that asthma is a disease of digestion and the digestion depends upon the diet we take. The diet should be extremely limited and restricted for the first week or two, after which we may gradually increase the list. Every physician should learn the art of cooking. And when I speak of cooking, I have in mind only scientific cooking, which not only should please the eye and taste but, especially, should have regard for the chemical composition of the food itself and of the mode of its preparation. Having studied this subject and experimented in it for many years, I have long ago come to the conclusion that the printed diet lists, so frequently used by the physicians, are not only useless but very often quite harmful. It is of no use to prescribe a diet for an Irishman which is well suited for the Italian or vice versa. The food of one nation may differ wholly from the food of another nation. Nay, even in the same nation the food and customs of one locality may differ entirely from those of another locality. The physician must bear all this in mind. My usual procedure is this: I have the patient submit to me a list of the foods which he has been wont to take, and he must tell me, if he can, how each and every dish is prepared. We then go through this list and make whatever changes I find necessary. In this way the patient retains more or less his accustomed food and is well satisfied. Tea, coffee, cocoa, beer, wine, greasy foods, spices, and acid foods should be absolutely interdicted; also such as contain or produce gases—beans, peas, cabbages, and radishes. When the patient manifests a desire for sour milk, we will find that a prescription calling for dilute lactic acid with nux vomica or strychnine will be well tolerated and do good.

The diet rules just mentioned must be looked upon as being merely in the nature of a sketch, as stating only the principles. In our big city we come across all nationalities and therefore meet all kinds of foods and dishes. But in the smaller localities, where the same dishes are used by nearly all the inhabitants, the problem of the selection of the suitable diet will be markedly simplified and the physician may soon adopt a certain diet rule which

will be most excellent in his locality although perhaps not so suitable in another. Common salt is not tolerated by asthmatics and very little only should be permitted. It would seem that it is the chlorine which acts badly, as by substituting the sodium bromide for the sodium chloride the patient gets along better. In this case the sodium bromide is to be used exactly in the same way as the ordinary salt, without regard to dosage.

Concerning the treatment of the constipation, the physician should bear in mind that, barring adhesions or other mechanical impediments to the lumen of the intestines, constipation is caused by the absence of peristalsis. Peristalsis is produced by the contraction of the muscular coats of the intestines. When the muscularis does not contract there cannot be peristalsis and therefore no bowel movement. When, instead of the contractions which produce the peristalsis the intestines are distended by gas, the absence of the muscular contractions is responsible for the constipation. It follows, therefore, that the gas distention of the intestines has constipation as a necessary consequence. A very quick means to relieve the intestines from gas is the enema. I have employed this thousands of times and have demonstrated its efficacy ever since I got into practice. All that is necessary is a fountain syringe with a small rectal nozzle and warm water. The position of the patient must be such as to favor gravitation of the water up to the ileocecal valve. This is accomplished by posture. By preference, the patient is put on the floor on his back with the pelvis suitably elevated about six inches. The nozzle is then lubricated and introduced into the rectum and the water is allowed to flow. No colon tube is ever necessary or called for and its use betrays a lack of the most rudimentary knowledge of physics. If there is room for a colon tube, there surely is room for the water; the colon tube might do harm, the water never. There is no such thing as a definite quantity of water which is to be permitted to flow into the intestine; the patient gets as much water as he can stand, be that quantity more or less. In the administration of enemas to the child we simply wait until the water is shot back.

The patient should be told not to go to bed early. Rather, he should go to bed about 11, or perhaps a little later. If he goes to bed early he may sleep 5 or 6 hours and then wake around 2 o'clock in the morning and the chances then are that he will remain awake as he already has had sleep enough. The remaining awake the rest of the night has a depressing influence upon the patient, who is so easily disheartened.

Of the various complications which may coexist with asthma I wish to mention edema of the legs, which becomes ascending, involving the genitals, pelvis, and then abdomen. I have seen this several times. The patients recovered under treatment with calomel and the compound jalap powder, together with bicarbonate of soda every few days. In one case, a man 71 years old, the edema took on alarming proportions. His legs became livid, cold, and so swollen and heavy that they had to be raised for him and only with difficulty could he raise them himself with his hands. Also his genitals became very edematous and fluid began to accumulate in the abdomen. Notwithstanding this, under the calomel mixture alternating with a mixture of potassium citrate and magnesium sulphate with the fluid extract of digitalis the edema disappeared.

The Treatment of the Asthmatic Attack.—A long list of drugs has been advocated to check the attack. I know of nothing better than the emptying of the stomach and of the bowels. Not always, however, can we get the consent of the patient or of his friends, who look upon these procedures as being too heroic. The stomach may be emptied by the stomach tube or by an emetic, and the tube is to be given preference. To those who are not used to the handling of the tube, I would recommend the employment of my stomach tube director, which was described in the MEDICAL RECORD August 9, 1896. The bowels are emptied the quickest by an enema.

To check the spasm many drugs are used, but the relief is only temporary. The next commonly employed are: Inhalations of the smoke of stramonium either from the ignited pulverized leaves or the leaves made in the form of a cigarette. Also nitre paper is burned and the fumes are inhaled. This nitre paper can be made by saturating blotting paper in a saturated solution of potassium nitrate and then drying the paper. Some use chloroform inhalations and some amyl nitrite. Hypodermically adrenalin and morphine are used. None of the drugs here enumerated, and there are a good many more proprietary compounds, gives anything else than temporary relief, and their use should be discouraged.

Summary.—The centuries' old conception of asthma as being due to a spasm of the bronchial tubes has been based entirely upon a speculation and not upon actually ascertained facts. That erroneous understanding has been passed from generation to generation. Comparing the clinical picture of the behavior of the chest in cases of known and demonstrated obstruction to the ingress of air, with the clinical picture of the behavior of the chest in an attack of asthma, we find a most marked and highly contrasting condition. In cases of known and demonstrable obstruction the supraclavicular fossæ and the intercostal spaces are drawn in; in asthma these are bulging. In true obstructions the inspiration is prolonged and labored; in asthma it is the expiration which is prolonged and labored. There is no reason why asthma may not be complicated by any other pathological condition, among others also by cardiac, renal, or nasal diseases. But the mere association of these diseases does neither justify nor permit the assumption that asthma is the result of such pathological conditions; the mere fact of their association does not justify the assumption that they are the cause of asthma. The underlying cause of asthma is the overproduction of irritating gases in the gastrointestinal canal, which, operating physically and chemically, produce the asthmatic paroxysm. Physically, by overdistention of abdomen and of the pressure upward of the diaphragm against the lungs, whose expansion is violently interfered with. Chemically, by irritating the esophagus and pharynx, which irritation the patient attempts to clear away by the act of coughing. So long as the irritation continues, so long continues the ineffective coughing. The longer the irritation continues, the more violent becomes the act of coughing, the consequence of which is dilata-

tion of the pulmonary air vesicles, which may and often enough does terminate in emphysema of the lungs. The asthmatic paroxysm ends when the irritation in the esophagus and pharynx have been removed, partly by neutralization of the irritation and partly by its dilution with pharyngo-esophageal secretions. Asthma is curable in about four months. This cure must be taken in the sense of the cure of any other conditon; an organ once cured will remain cured if it is not again subjected to the causes which originally caused its disease. Asthma will remain cured if the patient will not again abuse his digestive organs. Thus the prognosis of asthma is excellent, no matter how long the condition has existed. In the curing of asthma both the patient and the physician must be very patient and persevering. The physician must be conscious of the fact and must so inform his patient, that the attacks are not going to stay away immediately after our treatment has begun, but the attacks will gradually lessen in severity and frequency until they entirely die out.

616 Madison Avenue.

POST-INFLUENZAL ALOPECIA*

By C. AUGUSTUS SIMPSON, M.D.,

WASHINGTON, D. C., AND NEWPORT, R. I.

DERMATOLOGIST TO THE EPISCOPAL EYE AND THROAT, GEORGE WASHINGTON, AND WASHINGTON ASYLUM HOSPITALS, WASHINGTON CITY, AND ST. ANN ORPHAN ASYLUMS.

The three dermatologists who have contributed most to our knowledge of scalp lesions are Sabouraud, Unna, and F. Pincus. Most of Jackson's and McMurtry's book is taken from Sabouraud's works. The author fully quotes the above, especially F. Pincus, in whose office and laboratory he spent several months.

Following the recent epidemic of influenza, the dermatologist has had a splendid opportunity to note what a fearfully destructive effect it had on the skin appendages, hair and nails. The individual cases can be compared only with profound and long drawn-out typhoid infections. Besides the anemia, nervous exhaustion, and general weakness from which the majority of these patients suffered, and with which you are quite familiar, the enormous number of cases of alopecia gives one a good index of the intense virulence and tenacity of the disease.

To be of benefit to those who come into contact with these patients, to prevent some misconceptions of the past, and to give some useful hints on the hygiene of the hair, are the sole excuse for this paper.

The average physician should be in a position to give useful advice on dermatological lesions with the same familiarity as on other branches of medicine. Failure to meet these just obligations is a prime cause for the perfect deluge of beauty parlors and hair restorers which assail one's eyes and nostrils in every city. A little of such advice to your convalscent patients will be highly appreciated. I have known ungrateful patients to be most indignant with their doctors because they treated the loss of their hair as a joke, they admitting at the same time that the physician's skill had saved the lives of one or more members of their families. For a physician to advise having the head shaved or hair clipped a number of instances of which I have known, is to gain the lasting enmity of his patient. Only a few weeks have passed since this city was shocked by the suicide of a beautiful and wealthy woman who had a mild case of seborrhoic dermatitis of the scalp for which someone insisted she must sacrifice her hair. I will agree with you that such unreasonableness is absurd but these very particular patients retain their views just the same.

Happily the prognosis in uncomplicated post-influenzal alopecia is very good, as it is in all sympathetic alopecias, but it is a mistake to suppose that these cases will return to normal without any attention. The probabilities are that many will never have the quality and quantity of hair they once had. How many of your female patients trace their thin hair to a previous attack of typhoid? Yet everyone knows that the hair is quickly regenerated after this illness. However, these uncomplicated cases as a rule quickly respond to a mildly stimulating lotion massaged into the scalp once a day.

It is with the prophylactic and curative treatment of post-influenzal alopecia complicated with pityriasis and seborrhoic dermatitis that this article is chiefly concerned. I speak of prophylactic treatment because my clinical experience leads me to believe that this tremendous loss of hair following acute infections can be prevented in many instances. I believe the condition is primarily one of nutrition of the hair dependent on the circulation.

Unna claims that the loosening and shedding of the hair oftentimes is due to the character of the blood supply. He explains this by showing that the middle region of the rair follicle is supplied by arterial twigs from the subpapillary circulation, and the papilla of the hair is nourished by little arteries from the deeper arterial circulation of the cutis. Therefore the middle follicle region must participate in the disturbances of the subpapillary circulation while the papilla is relatively free from this influence. Thus any lessening of the nutritive supply of the papilla or any increase in that from the subpapillary circulation to the middle follicle region must cause a preponderance of nutrition in the middle over the lower follicle region. This would necessarily cause an increased growth of the prickle cell layer of the middle follicle region and an increased pressure upon the hair. Then either the circumference of the hair cylinder would be lessened or the hair itself would be pressed out of the follicle and raised from the papilla. The latter is what actually takes place. The bed hair is shoved higher and higher up so long as it remains in the middle third of the follicle; that is, just below the mouth of the sebaceous gland—the circulation becomes again equalized and the hair ceasing to grow, and being separated from its bed in time falls out.

Apropos of these remarks on the pathology and prophylactic measures I will say that I know of

*Read before the District of Columbia Medical Society, January 29, 1919.

at least six patients who were and are applying a preparation of sulphur, salicylic acid, and pilocarpine for seborrhoic dermatitis of the scalp. All of them were victims of severe influenza infections and today, more than two months since their recovery, their hair fall has not been excessive.

Pilocarpine is the only drug that is known to promote the growth of hair, naturally, in the presence of a hair follicles. It is quite possible that the specific action of the pilocarpine combined with daily massage so stabilized the scalp circulation that the majority of the hairs did not suffer a separation from the papilla. Certainly if it is possible to get such a result in six cases the method at least calls for a more thorough trial as the trouble is negligible. One recognizes the difficulty of carrying out any treatment other than that directed toward the influenza, although it is safe to say that while the doctor is using his skill and energy to save the patient's health, she is many times worrying about her hair. This statement may be ridiculed by those who have not come in contact with such patients but I have often wondered if the average woman's soul is not bound up in her hair. For her to be even threatened with baldness will often turn an apparently normal woman into a hysterical, weeping, neurasthenic creature without a bright prospect in the world.

In patients with post-influenzal aloecia complicated by pityriasis steatoides or seborrhoic dermatitis, we are confronted by a condition that demands energetic treatment if we expect the woman to retain her normal quantity and quality of hair.

Here we have a scalp lesion which is slowly destroying the hair follicle, transforming root hairs into bed hairs and leading to atrophy, after which all forms of treatment are useless. If the disease is of some duration noticeable hair fall will have already become evident. The patient sees that her hair has become finer, shorter, thinner, possibly with split ends and maybe very oily. Add to this the tremendous constitutional disturbance and hair fall resulting from a virulent infection, such as the past epidemic of influenza, and the result is to be foreseen. Under such a severe added handicap it is a mistake to suppose that an already damaged hair follicle will produce a strong, vigorous, normal hair.

Perhaps the patient already has incurable seborrhea for which our remedies are only palliative. She is usually, however, fortunate enough to have one of the other scalp lesions which we can successfully combat.

It takes a careful examination to differentiate between the two and here a snap-shot diagnosis will lead to grief as in any other branch of medicine.

The patient must take down her hair and be seated in a good light in order to make an intelligent examination and diagnosis possible.

The following diseases are to be sought for: hyperidrosis, seborrhea, pityriasis simplex, pityraisis steatoides, and dermatitis seborrhoica.

If the patient is an adult ringworm can be excluded, while alopecia areata can be diagnosed at a glance.

Hyperidrosis capitis is closely allied to hyperidrosis of the palms. It usually occurs in neurotic individuals who are anemic and whose bodily vigor is below par. It does not cause baldness and is not associated with dry or greasy scales, crusts, or seborrhoic filaments. The excessive production of sweat and moisture of the hair are the most troublesome features of this disease. The treatment is most satisfactory in those cases that can be built up by general tonics and attention to the hygiene. Ergot and atropine act only temporarily. The *x*-ray, our best treatment for hyperidrosis, cannot be used as it destroys the hair follicles along with the sweat glands; locally some such astringent as zinc and alum in alcohol and other lotions are helpful.

Seborrhea is an oily condition of the scalp due to hypersecretion by the sebaceous glands and the formation of minute, white, vermicelli-like masses which can be squeezed out of the dilated follicles. The disease is caused by an infection of the sebaceous glands the nature of which is unsettled. Sabouraud claims his microbacillus is the organism.

In uncomplicated cases there is an absence of desquamation and the hair is free from dandruff. The scalp may share in a general over-activity of the sebaceous glands when the nose and middle forehead will also be greasy. As to be expected, it is a disease of young people under thirty years of age as a rule. When seen in older persons it seems to be of a milder type and more localized to the scalp. The hair is very oily, shiny, and sticks together as though it were buttered. Itching is very often a most troublesome symptom. Hyperidrosis may add to the unpleasantness.

The pathology shows an hyperthrophy of the sebaceous glands with no signs of degeneration, but at the same time progressive atrophy of the hair follicle and destruction of the papilla. Plugs of sebaceous material fill the orifices of the sebaceous gland.

The disease is incurable and leads to baldness if not treated. Continuous treatment will hold it in check but, according to Sabouraud, if this is stopped the disease is sure to reappear.

While a cure is impossible in these cases, it is remarkable how much we can relieve the symptoms and limit the hair fall. For this we have two agents that are far superior to anything that has ever been placed in the hands of the profession, viz.: the Kromayer lamp and colloidal sulphur.

With the lamp we can often stop the itching in one treatment, while all dermatologists agree that sulphur is the best drug we have in dealing with seborrhoic lesions in any location. Unfortunately, the usual forms of sulphur are insoluble which necessitates our incorporating them in cold cream, lanolin, or other greasy basis, which means that a patient whose hair is already reeking with oil and grease pays the physician perfectly good money to have more salve and grease applied to her head.

Colloidal sulphur is soluble in water and diluted alcohol. I prescribe it in concentrated solution, to be applied with a dropper. In this manner the patient gets the benefit of our best drug and in

stead of adding to the pathological quantity of oil on the scalp the lotion rather decreases it.

Once the condition is under control the patient is given a pleasant alcohol or ether lotion of 3 per cent. salicylic acid and resercin which she is requested to use at intervals for a long time.

Another scalp lesion that complicates post-influenza is pityriasis or scaling. Pityriasis may be the simple variety, more often it changes into pityriasis steatoides. Pityriasis simplex is a non-inflammatory, powdery exfoliation of the horny layer of the scalp—dandruff. Should this condition become excessive it becomes a disease and requires treatment. The scalp is dry and the hair is dry, lustreless, and dead looking.

The scaling is the result of increased development and exfoliation of the horny cells and has nothing to do with the sebaceous glands which were the seat of the pathology of the proceding scalp lesion, seborrhea. The entire scalp is usually involved yet a close examination shows no signs of inflammation, only a ceaseless scaling.

Two great predisposing causes of this lesion are general malnutrition of the patient caused by bad hygienic surroundings, some such constitutional disease as gout or nephritis, and direct irritation of the scalp by a patent hair dye or restorer, which contains an excess of free alkalies or other irritants. Many of these patients have been overtreated and require a rest. Jackson and McMurtry say that this lesion may persist in this uncomplicated form throughout the life of the patient and in this case will not cause alopecia. A bland oil like oil of sweet almonds is usually indicated. Frequently, however, the simple pityriasis becomes pityriasis steatoides which results in alopecia.

The great majority of cases of influenza alopecia are complicated with pityriasis steatoides. Only by close attention to the history and a careful scalp examination can one tell which condition is at fault. To expect full regeneration of the hair from a follicle already damaged by pityriasis steatoides is to subscribe to Eddyism. Are the ravages of one disease to be compensated for by the destruction caused by another?

In pityriasis steatoides the scalp is covered with yellow, adherent, coarse and fine, greasy crusts. The underlying skin usually shows signs of inflammation and redness, but never vesiculation or exudation as in eczema. The disease usually involves the top of the scalp first, later attacking the temporal areas. The history of these patients usually reveals that this scalp infection follows a visit to some unclean beauty or hair parlor. Many patients complain of severe itching. The hair becomes oily yet, unlike the condition in seborrhea, the sebaceous glands are not hypertrophied. The follicles are filled with a plug of cornified cells shaped like a nail with the point downward. The papillæ atrophy and alopecia is the result.

One must realize that one is most often dealing with a very particular woman who while wishing relief does not expect to forego her pleasures or social activities in the process. Rather than be greased and perfumed up with nauseating tar, mercury, and sulphur ointments, which are more suitable for dispensary patients, she will many times bear the loss in silence and buy more hair to take the place of that lost.

The Kromayer lamp will often clear up these lesions without the aid of drugs or salves. Itching ceases after one or two treatments—hair fall decreases almost as quickly and it is only a short time (an average of four treatments) before we have the disease under control. To deny our patients the benefit of the Kromayer lamp is to retard their cure and add to their unhappiness and misery.

Five years experience with the lamp has convinced me of its real value in these cases of pityriasis steatoides associated with alarming hair fall. I have had good results with it in patients who have failed to get relief from salves and lotions not only in my hands, but in those of some of the best-known and most skilful dermatologists of America and Europe.

For patients whose hair continues to be oily even after the hair fall has ceased, I once more rely on the colloidal sulphur in concentrated solutions. In fact I often prescribe the sulphur which the patients use at the same time the lamp exposures are given. For this reason, some patients have the combination rather than each individual agent to thank for their relief.

I first saw the good effects of colloidal sulphur in Max Joseph's clinic and it has always been a surprise to me that American dermatologists have not more frequently availed themselves of its real advantages.

1219 Connecticut Avenue.

A SIMPLE URINE TEST FOR ACIDOSIS.

By CLIFFORD MITCHELL, M.D.,

CHICAGO, ILL.

While it is true that, in some cases of acidosis, we find a high titration acidity of the urine, this acidity cannot be solely depended upon as a sure diagnostic sign of the condition. In proof of this it is merely necessary to draw attention to the fact that after drinking lemon phosphate or other popular acid drink, or after taking acid solutions as medicines, the titration acidity of urine may be greatly increased. Conversely the fact that the urine may happen to have a low titration acidity is no proof of the absence of acidosis. Hence sole reliance upon the determination of urine acidity should not be placed.

It is true that the presence of acidosis may in some cases be revealed by the detection of the acetone bodies in the urine, but of these the only one readily found by simple chemical tests is diacetic acid. And when it comes to the detection of diacetic acid there are fallacies in the test which may lead to errors of diagnosis on the part of the clinician. For example, unless the physician uses the ferric chloride solution in sufficient percentage strength, Gerhardt's test, the one usually employed, may fail to give a decisive reaction. Again in the presence of the products of coal tar derivatives in the urine, as, for example, saccharin, used so frequently by diabetics as a sweetener, the red color observed, when the ferric chloride solution is added,

may be due to drugs and not to diacetic acid. Moreover alkaline urine turns red when ferric chloride solution is added to it, which if not known by the clinician may give rise to a serious error in the diagnosis. Lastly for making the ferric chloride solution it is necessary to procure the so-called iron chloride in lumps, which is to be had only from dealers in chemicals.

In cases where the clinical features suggest the presence of acidosis but when the acetone bodies are absent, and also as a diagnostic measure in any suspected cases, it is the custom of some clinicians to make use of the determination of the carbon dioxide content of the alveolar air. Without discussing the merits or demerits of this procedure it may be remarked that special apparatus is necessary for making this test, and that this special apparatus is to be had only from dealers in scientific instruments and apparatus, hence may not be available in smaller communities.

Lastly, it is held by modern authorities that the diagnosis is best accomplished by the conjoint examination of the blood and urine. Without denying the scientific truth of this statement, it may be remarked that this conjoint examination can be made only under especially favorable circumstances, and is rather a matter for consultations than for the routine practice of medicine.

What is wanted by the busy practitioner is a simple urine test which shall be trustworthy, inexpensive, thoroughly practical and readily accomplished without the need of special apparatus, special skill, or chemicals difficult to obtain. In other words a test which can be made with materials procurable from the average drug store. Such a test the writer has devised and used successfully in the case of two types of acidosis, namely in that of diabetes mellitus, and in that of the pernicious vomiting of pregnancy. Without waiting for trial of the test in cases of the food intoxication of children, in uremia, and in other conditions in which acidosis has been thought, claimed, or asserted to be present the writer offers his new urine test to the profession, having by two years' study and trial of it proved to his own satisfaction that it is practical in diabetes and in pregnancy.

The foundation of the test rests upon the fact that urine has the property of decolorizing iodine in aqueous solution, that is iodine in solution in potassium idodide solution, for example, the so-called Lugol's solution. The truth of this can easily be ascertained by the following simple experiment: to one liter of water add 3 c.c. of Lugol's solution and mix thoroughly. A yellow liquid results which has a peculiar reddish tint, and a bright color. Pour 10 c.c. of this liquid into a small white dish, and with the aid of a medicine dropper add urine drop by drop, with stirring, to the liquid in the dish. After 5 or 10 drops of urine have been added it will be seen that the color of the yellow liquid begins to fade, and that after some 20 or 30 drops have been added the color is discharged entirely. The decolorization is not due to dilution with urine, as can be proved by performing the experiment with water instead of urine.

After several years of experiment with the urines of various diseases the writer found that the urine of diabetic coma, and of the pernicious vomiting of pregnancy, had a greater decolorizing power, so far as iodine was concerned, than that of other conditions. In other words the urine in the acidosis of diabetes and of pregnancy contains a substance which is particularly well able to destroy the yellow color of iodine.

Hence an iodine test for acidosis has been devised which can be used quantitatively, and by use of which can be entered day by day on the case record the figures indicating the degree of acidosis of the patient, as shown by the toxine output in the urine. The writer is aware that the claim he is making is no small one, but fortunately the process is so simple that the truth of the matter can be very easily verified without expenditure of much time or money. The best way to apply the test, so far discovered, is the following: to 145 c.c. of water (hydrant water will do) are added 3 c.c. of Lugol's solution and 2 c.c. of a saturated solution of picric acid, the whole being thoroughly mixed. The result is a fine clear reddish liquid of bright color. Pour this liquid into a white dish and heat it. The writer heats it on the water bath to a temperature of 180° F., but if a water bath is not available it may be heated over the flame until fumes are abundantly given off, boiling being avoided by turning down the flame sufficiently. When thus heated, the urine is added as quickly as possible but in small amounts at a time, the writer using for this purpose a graduated burette. If, however, a burette is not available, a small graduate or graduated bottle may be used from which to pour the urine into the hot liquid. It will be found that in acidosis the amount of urine needed to turn the bright red color to a bright yellow color is small, and the smaller the worse the case. In severe cases 2 or 3 c.c. of urine will almost immediately discharge the red color. In cases of moderate severity 8 or 10 c.c. may be required. Normal urines do not usually affect the color in smaller amounts than 15 c.c., except possibly in unusual conditions of concentration, where the amount of urine in 24 hours may be but a few hundred cubic centimeters. In most cases of normal urine, of specific gravity ranging from 1,015 to 1,020, the amount of urine required to effect change from red to yellow is around 20 c.c. or even higher, as high as 50 c.c. in some cases.

There is no trouble about the end reaction in this process as the mixture remains fairly clear, sometimes entirely clear. If the change from red to yellow is not easily recognized, it will be of avail to have near by in another white dish about 150 c.c. of a saturated picric acid solution for purposes of comparison. With practice the titration can be made so closely as to repeat within a fraction of a c.c., provided a constant temperature is kept and if the process is rapidly performed.

If from day to day the color is discharged by less and less urine, the case is growing worse. If, on the other hand, more and more urine is daily required to turn the red to yellow, the patient is improving.

The test can be made in the cold by timing. That is to say, to a given amount of the liquid is added a smaller amount of the urine to be tested, and the time in seconds, minutes, or hours required for the change of color is compared with the time required for an equal amount of normal urine to effect the

change of color. The writer, however, prefers the method in which the urine is heated as more rapid and more trustworthy.

It is true that picric acid is to be had, as a rule, only from dealers in chemicals, but it is also true that it is not absolutely necessary for use in the test. Omitting picric acid entirely, the end reaction may be obtained closely enough for clinical purposes. The writer uses picric acid because it enables him to obtain the end reaction more closely. In other words the general practitioner for his own purposes needs only a small white granite-ware dish which will stand the naked flame, a graduated bottle which is now easily had or a small graduate the past few years, the author of the article regists, Lugol's solution, which is easily obtainable, and something to stir with, a spoon sufficing if a glass rod is not available.

25 East Washington Street.

Medicolegal Notes.

Malpractice—Damages—Privileged Communications—Waiver.—In an action for damages by a patient against a physician for injuries for alleged negligent treatment, it appeared that the defendant maintained an office in the city of Rochester, and styled himself an "osteopathic physician." In May, 1917, plaintiff had a severe headache and went to defendant's office for treatment, and defendant treated him, receiving pay for his services. The entire treatment did not last over five minutes, and consisted in defendant having plaintiff get on a table and relax his muscles, whereupon defendant took hold of plaintiff's head and gave it a wrench sidewise, also giving it a rotary motion, using great force in the operation. Immediately everything became blurred to the plaintiff, and he felt dizzy, but as soon as the treatment was concluded, and he had paid defendant he left the office and returned to his own place of business, where he stayed for a short time. The same condition of dizziness that had developed in defendant's office continued, and plaintiff had pains down the back of his neck and down his spine. After obtaining a lunch in a restaurant, plaintiff went to his home, arriving there about a quarter of 8 in the evening. A short time after plaintiff arrived home he went to bed, was sick at his stomach, and went into an unconscious condition, and remained so for a considerable time.

Medical attendance was obtained, which continued for some weeks, but he was never restored to the same condition of health he enjoyed before defendant treated him. On the contrary, there was evidence in the case that he lost a great deal of flesh, that the seventh cervical vertebra had been fractured by defendant's treatment, which resulted in plaintiff's partial paralysis and subsequent condition as described by the witnesses, and that it was doubtful whether he would ever fully recover his health. In fact, medical experts called by the plaintiff gave it as their opinion that he would not fully recover. Of course experts called in behalf of defendant denied that plaintiff's condition was attributable to defendant's treatment, and stated that his injuries were not permanent in their character.

There was ample evidence in the case upon which the jury could base a finding that the condition of plaintiff's health was good, excepting for an occasional headache, right up to the time defendant treated him, but immediately following that treatment the condition of dizziness, pain in the back of his head and down the spine, and partial paralysis followed. The questions whether or not this condition was the result of defendant's treatment, whether or not his treatment of plaintiff was too severe, and he was negligent therein, and whether or not defendant exercised ordinary skill and reasonable care in the treatment of plaintiff, were all questions of fact for the jury, and their findings in favor of plaintiff were held supported by sufficient evidence. Likewise, the question of damages was clearly within the province of the jury. It having been found as a fact that patient's condition was attributable to defendant's improper and negligent treatment, and that plaintiff was entitled to some damages, the amount to be awarded was for the jury, and in this case, in view of the evidence, it was held that the amount awarded was not excessive.

Defendant urged that a new trial should be granted on the ground that the testimony of Dr. Woodruff, a physician called by defendant, was erroneously excluded. It was held there was no error in excluding that testimony. When plaintiff was on the stand for his direct examination, not one word of testimony was given by him as to any professional services that had been rendered to him by Dr. Woodruff, but on his cross-examination defendant brought out that in 1909, and also in the fall of 1917, plaintiff had been treated by Dr. Woodruff, going into some detail as to the nature of his ailment. Then on redirect examination plaintiff was asked to explain further with reference to the treatment given him by Dr. Woodruff, and which had been pried out of him on his cross-examination.

The defendant called Dr. Woodruff to give testimony as to the treatment he gave plaintiff, and as to what ailed him. It will be understood that these treatments were not at the time, or anywhere near the time, he was treated by defendant, and were wholly disconnected with the transaction in question. The plaintiff had consulted Dr. Woodruff on these occasions for some other difficulty, and the relation of patient and physician had been established between them.

Any statements or communications to Dr. Woodruff at that time were held clearly privileged under section 834 of the Code of Civil Procedure.—Gunn v. Robinson, 103 Misc. (N. Y.) 547, 171 N. Y. Supp. 692.

Fee for Operation.—A physician and surgeon sued for medical and surgical services rendered by him, with the assistance of another physician and surgeon and two internes, in performing an operation upon the defendant's wife, whose throat had been cut practically straight through, severing the trachea, hyoid muscle, external jugular vein, and fascia and trachea between the larynx and hyoid bone. The operation consisted of cleansing the wound and sewing together the various structures severed, and required a degree of skill not possessed by the regular physician and surgeon. It was held that a judgment for $100 was not excessive.—Eddy v. Healy, 209 Ill. App. 270.

Care for Child After Birth—Expert Testimony.—Action was brought against a general practitioner and a hospital to recover for the alleged negligent care of the plaintiff's mother and of the plaintiff at the plaintiff's birth, whereby the plaintiff's eyes became infected and the infection through the negligence of the defendant physician was allowed to spread, etc. It appeared that upon the discovery of the infection, which arose some time after the plaintiff's birth, an expert was, upon the defendant physician's advice and with the consent of the plaintiff's parents, placed in charge of the case. The expert evidence showed that this was the proper and best practice for a general practitioner. The Illinois Appellate Division held the evidence insufficient to go to the jury as to the alleged negligence of the defendant physician. Whether a physician has treated a case skilfully is a question of science which must be determined, not by lay evidence, but by the testimony of skilful physicians and surgeons. Judgment for the plaintiff was therefore reversed.—O'Connell v. West Side Hospital, 209 Ill. App. 233.

Expert Evidence—Colle's Fracture.—To recover under an accident insurance policy for the loss of a hand through sustaining a Colle's fracture in falling, the plaintiff must show that the injury resulted in a total loss of the usual functions of the hand. The defendant in such an action may introduce expert evidence to show the nature of such a fracture and the effect of it.—Nashelman v. Grand Lodge, etc., 209 Ill. App. 636.

Medical Opinion Invading Province of Jury.—The answer of a medical witness to a hypothetical question and as to his opinion whether or not a connection existed between the supposed accident and the plaintiff's appendicitis several months later, that "this was a traumatic appendicitis due to this accident," was held erroneously admitted over objection, as invading the province of the jury.—Moffett v. Calumet, etc., R. Co., 209 Ill. App. 243.

Military Medicine.

Medical Officers Cited for Bravery.—Among the officers and men of the Twenty-seventh Division formerly the New York National Guard who have received divisional citation for meritorious conduct during engagements in France and Belgium are Lieut. Col. Walter C. Montgomery, Division Surgeon, and Lieut. Lee A. Hadley Medical Corps, 106th Infantry.

Ambulance for Red Cross.—An ambulance purchased by the councils and members of the Royal Arcanum in New York State was presented to the Atlantic Division of the American Red Cross in the Armory of the First Field Hospital, on March 1, and received by Dr. D. C. Smyley, associate director for the Medical Corps Service of the Atlantic Division.

Surgical Operations at Sea.—The United States Transport *President Grant*, which arrived in the Port of New York, on February 26, with a large contingent of returning officers and men, has a record of having had two major surgical operations performed during the voyage. The first operation was performed by Dr. C. D. Langhorn, the ship's surgeon, who removed the appendix from a fireman, on February 18. Dr. Charles A. Nassau of Philadelphia, attached to the Army Medical Corps, performed the second operation, amputating the left leg of a private. The engines were stopped during the operations. Both patients are doing well.

Illness in American Expeditionary Forces.—Illness among the American Expeditionary Forces showed a considerable increase for the week ended February 6. During this week there were 132 new cases of typhoid fever, which sets a new record for this disease during the present war. The total number of sick reported on February 6 was 79,069, of whom 59,325 were being treated for disease and the rest for injuries. Sick and injured returned from France from the beginning of the war to February 14 totalled 69,574, of whom 59,456 have been sent home since the armistice was signed.

New York Clinics Open to Military Surgeons.—The Society for the Advancement of Clinical Study in New York is making a particular effort to show courtesies to these military surgeons who are temporarily staying in New York and is sending bulletins of operations in the various hospitals of the city daily to these surgeons upon request. Application for such bulletins may be made by visiting military surgeons at the headquarters of the Society, the New York Academy of Medicine, 17 West 43rd Street.

Recent Report on War Deaths.—The War Department now announces that deaths in the American Expeditionary Forces and among troops in the United States from all causes numbered 107,444. In the Expeditionary Forces the total was 72,951. Of these, 20,829 resulted from disease, 48,768 from injuries received in battle, and 3,354 from all other causes. The deaths from disease among troops in the United States totalled 32,737 and from other causes 1,756, giving a total of 34,493. The deaths from disease exceeded the total battle casualties by 5,000.

Work of Development Units.—During the six months that the army development battalions were in operation nearly 250,000 men received physical and educational training. These development battalions relieved our fighting forces of over 200,000 unfit men, and for every unfit man discharged by the battalions there were three men returned to useful duty in the army. Of the men sent to the development battalions, of which there were 31 in this country, 38,466 were placed in the first class on re-examination, 42,738 in the second class, and 38,468 in the third class. Of men sent to the development battalions more than 34 per cent. were unfit for immediate duty because of contagious diseases, nearly 13 per cent. were disqualified because of foot conditions, and five per cent. because of heart trouble.

Turkish Casualties.—A report from Constantinople states that the losses of the Turkish army in the war are estimated at 948,477, including dead, wounded, prisoners and missing. The dead number 5,550 officers, and 431,424 men; the wounded 407,772, and the remainder are accounted prisoners and missing.

Deaths in the Service.—Major John Ravenswood Hicks, M. C., U. S. Army, of Staten Island, N. Y., a graduate of the University of Maryland, Baltimore, in 1893, died while on duty with the 302d Tank Corps, American Expeditionary Forces, on January 3, aged 46 years. Before entering the service he was ophthalmic surgeon to St. Vincent's Hospital, New Brighton, Staten Island. From 1902 to 1906 he was acting assistant surgeon of the United States Army, serving in the Philippines.

Lieut. William Shorter Bull, M. C., U. S. Army, of Irvington, N. J., a graduate of the New York Homeopathic Medical College, in 1914, aged 32, on duty with the 114th Infantry, Twenty-ninth Division, American Expeditionary Forces, was instantly killed, while crossing the River Meuse under fire, on October 11, 1918.

Capt. Alba Gustavus Walker, M. C., U. S. Army, of Houlton, Me., a graduate of the College of Physicians and Surgeons, Boston, in 1902, honorably discharged from the service in November, died in Edmundston, N. B., on February 4, at the age of 48 years.

Lieut. Martin Maximilian Holzman, M. C., U. S. Army, of New York City, a graduate of the College of Physicians and Surgeons, in 1915, aged 27 years, on duty at Fort Oglethorpe, Ga., died on October 28, 1918, from acute bronchopneumonia.

Lieut. Arthur Henderson, M. C., U. S. Army, of Kokomo, Ind., a graduate of Jefferson Medical College, in 1912, on duty at Fort Benjamin Harrison, and later at Camp Zachary Taylor, died in Fort Bayard, N. M., on November 30, from pulmonary tuberculosis, aged 32 years.

Asst. Surg. Guy Benjamin Taylor, Lieut. J. G., U. S. Navy, of Lexington, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1917, aged 25 years, who served in France until December last, when he was assigned to duty at the U. S. Naval Hospital, Brooklyn, died in that institution on January 21 from pneumonia following influenza.

Lieut. Bradford Ripley Alden Scott, M. C., U. S. Army, of San Antonio, Texas, a graduate of

the University of Texas, Galveston, in 1916, formerly a member of the staff of the Southwestern Insane Asylum, San Antonio, on duty at Brooksfield, Texas, died at his home on November 12, of pneumonia following influenza.

Major Theophilus Parvin Calpinger, M. C., U. S. Army, of Wallace, Ind., a graduate of the Indiana Medical College, Indianapolis, in 1907, assistant medical chief at the base hospital, Camp Logan, Houston, Texas, died at that post on January 10, four days after an operation for appendicitis, at the age of 38 years.

Lieut. Ralph Edwin Schrom, Asst. Surg., U. S. N. R. F., of Philadelphia, a graduate of Jefferson Medical College, in 1904, died from pneumonia following influenza, at his home, on January 26, aged 36 years. He was assistant surgeon to the Philadelphia Polyclinic and Strittmatter's Private Hospital, Philadelphia.

Lieut. Zack Jackson Moore, M. C., U. S. Army, of San Antonio, Texas, a graduate of the University of Texas, Galveston, in 1915, aged 32 years, on duty with the Expeditionary Forces in France, was wounded on March 24, 1918, and died from pneumonia at Woolrich, England, on October 26, 1918.

Lieut. James Andrew McQuillan, M. C., U. S. Army, of Jackson, Mich., a graduate of St. Louis University, in 1912, aged 30 years, while on duty with the American Expeditionary Forces in France was killed by a shell, near Valenciennes, on October 23, 1918.

Lieut. Henry Blender, M. C., U. S. Army, of Okeene, Okla., a graduate of the Keokuk (Iowa) Medical College, in 1907, stationed at Camp Greenleaf, Ga., died at that place from lobar pneumonia following influenza, aged 34.

Medical Director Aaron S. Oberly, U. S. N., retired, died at his home in Avon, Conn., on January 15, aged 82 years. He was a graduate of Yale University in 1860. In 1861 he was appointed assistant surgeon in the navy, and served with the He was fleet surgeon of the Asiatic Station in 1884. West Gulf blockading squadron in the Civil War.

Lieut. John Groat Corson, M. C., U. S. Army, of Binghamton, N. Y., a graduate of the University of Syracuse, N. Y., in 1915, aged 27 years, on duty with a medical detachment of the British Expeditionary Forces in France, from whence he was invalided to England, died in a hospital in London on October 23, 1918, from lobar pneumonia.

Lieut. Noah Norman McFarland, M. C., U. S. Army, of Memphis, Tenn., a graduate of the University of Tennessee, Nashville, in 1913, aged 28 years, died in Camp Greene, Charlotte, N. C., on December 16, 1918, from lacerated wounds on both sides of the neck, severing the jugular veins.

Lieut. Knight William Field, M. C., U. S. Army, of Dallas, Texas, a graduate of Tulane University, New Orleans, in 1900, died while on duty with the American Expeditionary Forces in France, on October 11, aged 42 years.

Lieut. Burton Paul Bradley, M. C., U. S. Army, of Rome, Ga., a graduate of Emory University, Atlanta, Ga., on duty at Camp Pike, Little Rock, Ark., died on October 16, aged 26.

Lieut. Harry Robinson Parker, M. C., U. S. Army, of Williamstown, W. Va., a graduate of the University of Vermont, Burlington, in 1907, aged 34 years, on duty at Hazelhurst Field, Mineola, L. I., died of lobar pneumonia on December 21, 1918.

Lieut. Stephen James Hawkes, M. C., U. S. Army, of Dover, N. C., a graduate of the University College of Medicine, Richmond, Va., in 1911, on duty at Camp Jackson, Columbia, S. C., died from bronchial pneumonia on December 14, aged 32 years.

Lieut. Bryant Carr Rudder, M. C., U. S. Army, of Walker Springs, Ala., a graduate of the University of Nashville, Tenn., in 1911, aged 32 years, died from bronchopneumonia while on duty at Fort Oglethorpe, Ga., on October 14, 1918.

Lieut. Hugh Zollicoffer Browne, M. C., U. S. Army, of Kosciusco, Miss., a graduate of Tulane University, New Orleans, in 1911, on duty at Fort Oglethorpe, Ga., died from acute bronchial pneumonia on Oct. 22, 1918.

Lieut. Glenn Elbert Haughey, M. C., U. S. Army, of Wakeeney, Kan., a graduate of the Kansas Medical College, Topeka, in 1908, died from acute bronchopneumonia, while on duty at Fort Oglethorpe, Ga., on October 24, 1918, aged 34 years.

Lieut. Matthew Joseph Foley, M. C., U. S. Army, of New Haven, Conn., a graduate of the Eclectic Medical School, Cincinanti, in 1917, died from bronchopneumonia at Camp Meade, Md., on October 10, aged 27 years.

Capt. John Hamlin Traylor, M. C., U. S. Army, of Cureo, Texas, a graduate of Vanderbilt University, Nashville, Tenn., in 1909, on duty at Camp McArthur, Texas, died from acute meningitis on October 26, aged 31 years.

Major James Harvey Todd, C. A. M. C., Toronto, Ont., a graduate of the University of Toronto in 1905, on duty at Quebec, died from pneumonia following influenza, on October 17, aged 35 years.

Lieut. John Richard Fischer, M. C., U. S. Army, of Utica, N. Y., a graduate of the Unviersity and Bellevue Hospital Medical College in 1917, aged 26 years, died from chronic pulmonary tuberculosis on October 31, 1918.

Lieut. Charles Francis Cropp, M. C., U. S. Army, of Independence, Ore., a graduate of Willamette University, Salem, Ore., in 1913, died from bronchopneumonia following influenza, on January 6, aged 33 years.

Capt. Orin Worrett Robe, M. C., U. S. Army, of Portsmouth, Ohio, a graduate of Starling Medical College, Columbus, Ohio, in 1891, died from chronic myocarditis, on October 25, 1918, aged 50 years.

Lieut. Murat Halstead Scott, M. C., U. S. Army, of Harrison, Ohio, a graduate of the University of Cincinnati, in 1914, died from lobar pneumonia, while on duty at Fort Oglethorpe, Ga., on October 19, 1918, aged 28 years.

Capt. Elton Bane Rogers, M. C., U. S. Army, of Winchester, Idaho, aged 38 years, a graduate of the Northwestern Medical School, Chicago, in 1907, died recently in France, where he had been in service since May 25, 1918.

Lieut. Harold William Brown, M. C., U. S. Army, of Jersey City, N. J., a graduate of Cornell University, in 1908, died while on duty at Camp Leach, Washington, D. C., on Nov. 3, 1918, aged 32 years.

MEDICAL RECORD.

DEATH FOLLOWING AN INTRAVENOUS INJECTION.

COURTOIS-SUFFIT and Giroux relate the following in the *Gazette des Hôpitaux* for January 23: A married woman, aged 30, having recently contracted syphilis, asked her physician for energetic treatment. The diagnosis having been placed beyond doubt, a colleague was called in and a course of intravenous injections of novarsenobenzol begun. The product used was guaranteed, and seven injections were made without accident, but 10 minutes after the eighth injection the patient went into coma and died in the office. A judicial autopsy made by the authors 48 hours after death revealed absolutely nothing to account for the sudden demise. The report of the circumstances of death brought out that the seventh injection had been without any warning symptom, so that the fatal eighth was undertaken with complacency. Only the first and second injections caused respectively slight general and local reactions. The benefits of the treatment had been conspicuous, and especially the mental state was satisfactory, the patient being in constant euphoria. In making the eighth injection, the left arm having shown too slight prominence of veins, the operation was performed on the right arm and the fluid was thrown in very slowly. After 4 or 5 minutes the patient rose from her reclining position and dressed. She appeared normal throughout. Upon stepping up to the physician in order to pay him, she suddenly staggered forward, and while saying that she was ill fell in a faint. Her eyes were wide open and staring and pupils dilated as she was seized with a general convulsion. She had numerous seizures at brief intervals, and vomited. The pulse was rapid and fine, and adrenalin was injected, but although the pulse improved the patient passed into coma, and her convulsive seizures continued to the end, death occurring two hours after the first symptoms. All drugs and manipulations used in reanimation did not apparently cause a rally. As the medical man was proved to have been blameless, one could only attack the treatment.

At last accounts, considerably more than 300 deaths of all kinds have followed injections of the salvarsans. The great majority of these followed the first and second injections, and in very many there was a period of latency which excluded them from comparison. In the majority, however, ill consequences were immediate. The injections cause a prompt vasomotor reaction like that produced by the nitrites, which is succeeded by the opposite or syncopal phase. As a rule, this behavior is benign. An analysis of 211 deaths which supervened soon after injection shows, as already stated, that the great majority occurred after the first and second. Only eight occurred after the fourth, and one each after the fifth, six, and seventh. The authors' case, therefore, establishes a record. No data are quoted for the very late cases, but for those which supervened after the third and fourth injections leptomeningitis, with or without other endocranial mischief, was present. In the authors' case the encephalon was absolutely intact. The clinical phenomena have a suggestion of anaphylactic shock, and may come under the head of anaphylactoid behavior. Ordinary anaphylaxis and arsenical intoxication may be excluded, but anaphylactoid behavior is a vague expression of conditions of very different kinds concerning which we know but little. Danysz has an hypothesis which in part covers the authors' case. It is the supposed property of arsenic to combine with calcium in the plasma and form insoluble particles which finally cause embolism. This phenomenon, however, is of rather early development, and the eighth injection would be too remote. To avert it one should, in theory, begin with small doses in the interest of acquired tolerance.

THE LABORATORY TYPE OF PHYSICIAN.

THE entire extent of the ramifications which connect physical and mental disease has not been explored, but as new facts are brought to light unsuspected relations crop up. For example, if we take the two common diseases of pulmonary tuberculosis and dementia precox we find a certain number of common factors. While no one would go so far as to place dementia precox among the causes of pulmonary tuberculosis, or vice versa, still we may venture to say that there is a peculiar type of mental make-up which on the one hand may develop dementia precox as the result of stress, and which on the other hand favors a mode of living which renders the individual susceptible to invasion by the tubercle bacilli.

Those of us whose lives have been lived in close contact with hospitals are familiar with a type of individual who goes through the following phases: He enters a hospital, and soon manifests a distaste for the society of the other members of the staff. He comes to meals late, and, retiring to his room immediately after supper, shuts himself up with his books for the evening. Soon he develops a taste for laboratory work, and gradually assumes charge of that department of the hospital, where he is able to isolate himself almost entirely from personal contact. Soon he exhibits peculiarities of conduct in his chosen domain. He complains that

persons disarrange his specimens and steal his laboratory fluids. He devises elaborate systems of concealment and disguises his materials by changing the labels on bottles, etc. He shuts himself in as completely as possible by closing all windows and doors and by keeping the room overheated he manages to secure a replica of the intrauterine life, as a certain school of psychologists would say.

Now all this, as we know, is very suggestive of the mental make-up and beginning symptoms of dementia precox, while at the same time the mode of living described is often found preceding pulmonary tuberculosis. The connection is easy to see. The type of person who tends to avoid society, to shut himself up in enclosed places, to neglect exercise and fresh air, is mentally a precox type and physically a tuberculous one. We have chosen our paradigm from the medical profession simply because it is the most familiar to us, but the members of other professions will be able readily to cite examples from their own professions of the type of thing meant. We do not, of course, have any reference to the sort of physician who is attracted to laboratory work by a natural gift for scientific inquiry, who chooses that line of work as another man might choose ophthalmology, gynecology, or whatnot. But we refer to the type which chooses hospital life first of all because it obviates contact with the public, and laboratory work next because it enables him to withdraw from his own conferees.

As psychiatry becomes more and more a part of general medicine, it may be that the early manifestations of abnormal traits and peculiarities of make-up likely to lead to social maladjustments or to modes of living incompatible with personal hygiene will be referred to neurologists and psychiatrists, and the mental conflicts, repressions, and inadequacies responsible for them pointed out so that they can be corrected before they become fixed.

SYPHILIS AND ITS RELATION TO INFANT MORTALITY.

While statistics are by no means infallible and sometimes even misleading, they are at least suggestive and afford an index of the progress or decline of any one disease. However, figures with regard to the prevalence of syphilis are not so alarming as they ought to be. Judging from statistics tuberculosis causes more mortality and sickness by far than syphilis and yet the medical man in his heart of hearts knows that syphilis even as a cause of death is almost as destructive as tuberculosis, and that, on the whole, it is a greater menace to the human race than any disease. With regard to infant mortality and syphilis, Dr. P. C. Jeans of St. Louis, writing in the *American Journal of Syphilis* for January, 1919, shows how deadly syphilis is to infant life. From statistics he gathers the following facts: Between 10 and 20 per cent. of adult males and about 10 per cent. of married women are syphilitic and a minimum of 10 per cent. of marriages involve a syphilitic individual. Seventy-five per cent. of all the offspring in a syphilitic family are infected. In a syphilitic family 30 per cent. of the pregnancies terminate in death at or before term, a waste three times greater than is found in non-syphilitic families. Thirty per cent. of all the children born in a syphilitic family die in infancy as compared to a normal rate of 15 per cent. Probably 25 to 30 per cent. of clinically syphilitic infants die as a result of syphilis. Only 17 per cent. of all the pregnancies in syphilitic families result in living non-syphilitic children who survive the period of infancy. About 5 per cent. of our infant population is syphilitic. According to St. Louis vital statistics, 3.5 per cent. of all infant deaths are ascribed to lues.

Syphilis is a potent cause not only of infant mortality but of ill health, and at the present time is the most important public health problem. Jeans is of the opinion that for the proper control of syphilis it is necessary to consider the problem from the standpoint that it is a communicable disease, rather than as a social or moral problem and that the primary point of attack in the prophylaxis of infantile or any other variety of syphilis is the adult carrier. Next in importance is the syphilitic mother. Finally, Jeans holds that there is no reasonable hope of preventing syphilis, consequently our greatest effort must be directed toward treating the disease early and well. In the case of infants the management must be in the hands of one who is not only skilled in the diagnosis and treatment of this disease but one expert in the science of infant feeding.

EUGENIC AND SOCIAL INFLUENCE OF THE WAR.

Professor J. A. Lindsay, writing in *Eugenics Review* for October, 1918, says in part that the most fundamental question of all is what will be the wastage. Dr. Louis C. Parkes reckoned the number of males in all the combatant nations, to the end of the year 1915, killed or unable to support a family, at nine millions. It would hardly be rash to assume that this figure has been doubled since the above date. A more detailed calculation is that of F. Savorgnan contributed to a recent issue of *Scientia*. In this article he calculates the number of males of military age in the belligerent nations, the average annual increase of this class in normal times, the probable losses in war, and the time which the various nations will require to recoup their losses. These figures work out as follows:

A—Germany. Men of military age, 13 millions. Annual increment of this class, 168,000. Probable losses in war, 15 per cent. Period necessary for recoupment, 12 years.

B—France. Men of military age, 7½ millions. Annual increment of this class, 19,000. Probable losses in the war, 17 per cent. Period necessary for recoupment, 66 years.

C—England. Men of military age, 9 millions. Annual increment of this class, 83,000. Probable losses in the war, 9 per cent. Period necessary for recoupment, 10 years.

D—Italy. Men of military age, 5½ millions. Annual increment of this class, 13,000. Probable losses in the war, 9 per cent. Period necessary for recoupment, 38 years.

The loss of life in war is a question not only of quantity but of quality. The casualties among officers have been exceptionally heavy. One of the most obvious results of the slaughter of young men in the war will be an accentuation of the disproportion between the sexes, which was already marked in the prewar period. Closely related to the question of man power, as affected by the war, are the questions of marriage rates, birth rates, and death rates. As for birth rates, a rapid and progressive fall has been in operation in most civilized countries during the past fifty years. The decline began first in France in the early days of the nineteenth century, but was not manifest in England and Germany until the last quarter of the century. War for obvious reasons tends to depress the birth rates. In invaded and devastated regions the whole machinery of family life is disorganized and the birth rate has fallen to one-half or even less of the normal figure. As regards venereal disease, an increase in the prevalence of these affections seems an inevitable concomitant of war and constitutes one of its most serious dysgenic factors.

Medical Men and Their Cars.

C. W. Brett, writing in *Medical Press* of January 29, 1919, points out that with so large a proportion of the medical profession of Great Britain actively engaged in the numerous theaters of war no light task has been thrown upon those who remained in civil life. In the country districts, where the population is spread over extensive, straggling areas, the difficulties have been enormous, and it has sometimes been impossible for medical men to get through the day's work. The time taken in transit in normal periods is always considerable, and the conditions that have prevailed within the last two or three years have been such as to make the question of transport one of a complex character. Like the medical man, the motor machine has been severely overtaxed, and in thousands of cases both have been more or less broken down. How professional men have prevailed over temperamental and physical disabilities no one knows, but the story of the motor machine is clear and well defined. Like the human system, metal machinery of all kinds can be made the victim of overwork, and it frequently breaks down under the stresses of modern usage. Volumes have been written upon the subject of metals and their diseases, but the field is a very wide one, and metallurgists are fully aware that the subjects of their study have by no means yielded up all their secrets. Indeed, at this moment an influential body of scientists in America is busily engaged in investigating the question of metal fatigue, and there is little doubt that in years to come much progress will be made along this line in metallurgical science. The abnormal use of vehicular and industrial machinery during the war naturally led to serious mechanical troubles, and one London company engaged in the art of metal fusion has recreated and brought back into commission over 50,000 derelict machines engaged on work of national urgency. The medical man, especially in rural districts, urgently needs transport facilities, and in case of motor breakdowns a speedy repair by a reliable process is of prime importance. Thanks to the studies made in the art of metal fusion within the past few years, the author of the article referred to says, it is now possible to reconstitute or recreate fractured parts, no matter of what kind of metal they are made.

Noma in the Adult.

This affection is so rare with us, and so little is known of its nature, that the idea of an autonomous affection might be dispensed with, and even the name might be withdrawn in favor of the generic term spontaneous gangrene of unknown nature. It is by no means peculiar to the mouth, for a similar affection occurs on the external genitals and anus. However, if we look upon it as a tropical and exotic disease, which rarely is seen in temperate climates, the idea of a special affection may be justified. As seen in temperate zones, it is a disease almost peculiar to children, which chiefly follows one of the eruptive fevers. In an article by Canuyt in the *Revue de laryngologie* for January 15, a case in an adult is described, the patient being an Annamite. The statement is made that noma is considerably more common in hot countries like Annam than outside the tropics, but perhaps it would be more correct to say that in the tropics spontaneous gangrene is apt to follow not only the eruptive fevers but typhoid, pneumonia, diphtheria, etc., and to attack adults as well. It is nearly 100 per cent. fatal. In France we see thrush develop under the same conditions as noma, especially in connection with poverty and physiological misery. The patient was brought to Bordeaux and entered the Indo-Chinese Hospital with paratyphoid fever. Even in the early days of the malady, gangrenous spots were seen on the gums. From these points the affection steadily spread until it involved a large area on the face. Within the mouth the gums only are mentioned as largely destroyed by the process, although the mucosa of the cheeks must have participated. The *B. paratyphosus* A was cultivated from the blood. The secretion of the gangrenous process swarmed with different kinds of microorganisms, but none of them was of a known gangrene-producing type. Anthrax and Vincent's disease could be definitely excluded. The disease progressed irresistibly and there was no response to treatment of any sort. Salvarsan, which has cured a few cases, was inert. The extension of the gangrene was notable in comparison with the average case. On the left side it extended to the root of the nose, having destroyed the entire cheek, while on the right side its area of destruction was more like that in the average patient. The age of the victim was 37 years.

News of the Week.

Influenza in Britain and Spain.—Deaths from influenza increased to an alarming extent in England during the week ending February 22. In ninety-six great towns of England and Wales the deaths from this disease totalled 3,046, compared with 1,363 the preceding week. In Greater London 974 died from influenza, compared with 451 the previous week. A report to the State Department at Washington announces that another epidemic of influenza has broken out in Barcelona, Spain, and is spreading to as great an extent as that of last fall.

Railroad Casualties.—The Interstate Commerce Commission reports that casualties on American Railroads during 1917 resulted in the death of 9,567 persons and the injury of 70,970.

Diphtheria Increases in New York City.—During the month of February there were in this city 1,130 cases of diphtheria reported to the Health Department and 150 deaths from the disease, as against 663 cases and 95 deaths during the same period of 1917. There are about 15,000 cases of diphtheria with 1,400 deaths annually in New York City. In view of these facts the Health Department has issued an announcement stating that it is prepared upon request to apply the Schick test to children and to immunize those found to be susceptible to diphtheria. The tests and injections are made at the various baby health stations throughout the city.

New York Doctors Oppose Health Insurance.—At a mass meeting of physicians, dentists and pharmacists, held under the auspices of the Kings County Medical Society, on February 24, resolutions were passed unanimously opposing the Donohue Bill, providing for compulsory health insurance, which is now before the New York State Legislature. The Bronx County Medical Society has also repudiated the bill. The Medical Society of the County of New York has been no less vigorous in its protests, and has voted certain amendments to the bill as it stands which it insists must be incorporated into this or any other bill, if legislation providing for compulsory health insurance is inevitable. A number of other county societies throughout the State have also voiced their protests.

Rush for Drugs to Meet Dry Situation.—According to a statement recently made by Health Commissioner Royal S. Copeland before the New York State Department of Narcotic Drug Control investigations being made by the Health Department show that the sales of narcotic drugs have been increasing at an alarming rate. One firm, he states, sold more such drugs during January than it sold during the entire twelve months of 1918. The demand during the month of February has been so great that this firm has been compelled to limit the amount sold to one person. It is believed that the enforcement of prohibition will bring a great demand for narcotics and that it is necessary to prepare to meet the situation. Dr. Copeland advocates the establishment of official narcotic drug stations where persons known to be addicts will be obliged to go and register in order to buy. Arrangements are being made to receive addicts, both men and women, on North Brother Island.

Endowment Fund as Memorial to Dr. Cragin.—An organization has been formed to raise an endowment fund of $100,000 to perpetuate the method of after care for maternity cases evolved by Dr. Edwin Bradford Cragin in connection with the work of the Sloane Hospital for Women. Dr. Cragin was so impressed with the value of "follow-up" work in maternity cases that he contributed largely of his own means to make the work possible. To continue and extend this work a committee has been organized composed of many conspicuous workers in behalf of social service and charity. Henry K. McHarg, at 40 Wall Street, has been put in charge of the contributions.

Brockton Medical Society Revises Fee Table.—The Brockton Medical Society, at its meeting on February 14, adopted a new schedule of fees in accordance with which ordinary house calls will henceforth be $3 instead of $2 and night calls between 7 p. m. and 7 a. m. will be $5 instead of $3. Ordinary office calls will be $2 instead of $1. Other figures on this schedule are as follows: Consultations, $5; telephone consultation, $1; ordinary obstetrical case, $25; operative obstetrical case, $30 to $50; etherization, $5 to $10; office vaccination, $2.

Medical Inspectors Organize.—The Medical Inspectors of the New York Health Department have taken preliminary steps toward the organization of a Council of the New York Civil Service Society by holding a meeting in the County Court House, Manhattan, on February 21. Representatives of the New York Civil Service Society made addresses showing the advantages of organization and a temporary organization was formed of which Dr. Maria M. Vinton is chairman, Dr. Maude Glasgow, secretary, and Dr. Theodore Lehman, treasurer.

Dr. Edward Wadsworth Peterson, having completed his service in the United States Army, has resumed his practice at 525 Park Avenue, New York City.

Dr. John A. Ferguson of Brooklyn has been appointed by Mayor Hylan to the position of Medical Examiner with the Municipal Civil Service Commission of New York.

Dr. Howard Lilienthal has received an honorable discharge from the Medical Corps, U. S. A., and has resumed practice at 52 East 82d Street, New York City.

Dr. James Alexander Miller, who assisted Dr. Livingston Farrand in the organization and prosecution of the anti-tuberculosis campaign in France, has received the decoration of a Chevalier of the Legion of Honor.

Dr. Samuel Lambert has tendered his resignation as professor of clinical medicine and dean of the medical faculty of Columbia University, to take effect June 30.

Child Welfare Work Resumed.—Dr. S. Josephine Baker, Director of the Division of Child Hygiene of the New York Department of Health, announces that the work of the New York Children's Committee, which was interrupted three months ago to release physicians and nurses for the fight

against influenza, will now be resumed. At the time of the influenza outbreak nearly 200,000 children were registered in the fifty centers of this city and about 50,000 children had been examined, and the mothers of these children were receiving advice and information. While the effect of the influenza epidemic on the death rate of children under five years of age is not as yet definitely known the increase is large. In 1917 the mortality rate among children under one year of age was 88 per each 1,000 births and in 1918 this had increased to 91.7.

The Cost of State Charity.—The New York State Board of Charities in its fifty-second annual report just made public shows that a total of $38,000,000 annually is being spent for maintenance alone. The report makes an urgent plea to communities to try to reduce these expenditures by "getting at the cause of poverty, crime and sickness." Communities are urged to action in the matter of child welfare, protection of children from immoral and deleterious physical influences, playground, and further progress in child labor laws. The report recommends that the problem of the feebleminded be handled more systematically and gives its support to health insurance, since the experts of the board have reached the conclusion that 78 per cent. of poverty in the State is due to sickness, and this results in an annual loss to the bread winners of the State of $500,000,000. During the influenza epidemic, the report states, there have been 27,296 cases of influenza in the 280 charitable institutions of the State and 4,105 deaths.

Drink Abstinence Believed to Lessen Insanity.—A report from the Health Office of Vienna reveals a considerable decline in mental disease which is attributed to the lessening consumption of alcolohic beverages, which are extremely high in price. The inebriates' ward in the Vienna Lunatic Asylum is closed for lack of patients.

February Traffic Deaths.—The report of the National Highways Protective Society, for February shows that 32 persons were killed by automobiles, two by trolleys, and six by wagons in the streets of New York in February. In New York State, outside of the city of New York, automobiles caused 23 deaths, trolleys four, and a wagon one. In February 9 persons were killed by automobile, two by trolleys and one by wagon in New Jersey. Ten persons were killed at railroad grade crossings in New York State and three in New Jersey during the month.

Funds Needed for Paralysis Victims.—The New York Committee on After Care of Infantile Paralysis, with headquarters at 289 Fourth Avenue, has issued an appeal for $75,000 so that children who have not recovered may continue to receive regular treatment. Since the epidemic of infantile paralysis 8,720 children have been cared for and 2,913 braces furnished. The entire receipts of the Committee have been $280,852, of which $278,321 was disbursed.

The Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases will hold a stated meeting at the dispensary, 41 East 123d Street, on Tuesday, March 11, at 8.30 P. M. The papers of the evening will be read by Dr. Seymour Oppenheimer on "The Importance of Blood Examination in the Surgery of the Nose and Throat," and by Dr. John Guttman on "Orientation and Equilibration."

Medical Society Elections.—The LOWNDES COUNTY MEDICAL ASSOCIATION, at its annual meeting, held at Valdosta, Ga., February 14, elected the following officers for the ensuing year: *President*, Dr. D. W. Freeman; *Vice-President*, Dr. Frank Thomas; *Secretary*, Dr. J. F. Mixon.

National Crusade against Venereal Diseases.—The Division of Venereal Diseases of the United States Public Health Service is starting a vigorous campaign against venereal diseases. Surgeon General Rupert Blue has sent out a letter to the physicians of the country directing attention to the danger of an alarming spread of venereal disease during the reconstruction period, and urging that prompt measures be taken to meet the situation. Among the striking things disclosed by the army statistics is the value of proper methods of control as developed in the treatment of venereal cases in the service. It is pointed out that the same methods of control will prove equally as effective when applied to venereal cases among civilians. Each physician is asked to give assurance of his support by signing and returning an enclosed card which will ensure his receiving a copy of the revised "Manual of Treatment of Venereal Disease," prepared by the United States Public Health Service in accordance with the latest methods of treating venereal disease in the army. An appeal is also made by the Public Health Service to all advertising media to cooperate in the fight against venereal disease. This appeal states that venereal diseases have been the greatest cause of disability in the army, the service having lost more days from disability due to venereal disease than from any other cause. From the time the United States entered the war in April, 1917, to September, 1918, such loss represented 2,295,000 days of service. Statistics show that approximately five-sixths of this burden was brought into the army from civilian life, and that only one-sixth was contracted after enlistment. Therefore the problem is to bring the source of venereal infection among the civilian population under control. This is important because it involves the industrial efficiency of the nation. Short decisive methods of attack must be used. Newspapers, magazines, and medical journals are therefore requested to give the subject as much publicity as possible. Since industry does not have a nation-wide medical organization similar to that of the army to cope with this problem, the responsibility rests on the individual physician. It is important that each member of the medical profession should understand the seriousness of the statements frequently made that a majority of physicians refuse to treat venereal diseases and that many of those who do treat them are careless in their methods. The United States Public Health Service finds that thousands of druggists are responding to the request of the Government that they discontinue the sale of remedies for the self-treatment of venereal disease. They have agreed to direct customers to competent physicians or venereal

clinics. Physicians are asked to cooperate by agreeing to have their prescriptions for venereal cases filled at high-class drug stores. This, it is pointed out, will result in a cooperative interchange, whereby druggists will not attempt to treat these cases and physicians will not enter into competition with druggists in selling the medicines.

Find Carelessness Cause of Accidents.—The Steel Corporation Bulletin publishes an analysis of 185,490 accidents occurring in its plants, from which it appears that carelessness is largely to blame for these industrial accidents. Of these 185,490 accidents only 4.36 per cent. were due to hot metal, fluedust, or flames which might be considered entirely distinctive of the steel industry. Nearly one-half, or 44.78 per cent. of these accidents were attributed to hand labor, and one-third of those were due to falling material. In carefully analyzing the cause of any 100 accidents it was found that 90 per cent. of them might have been prevented if a little more care had been used. It was found that mechanical safeguards did not play as important a part in accident prevention work as was supposed, though the guarding of machinery was nevertheless essential.

Obituary Notes.—Dr. Myron L. Chamberlain died suddenly at his home in Boston on February 17, aged 75 years. He was a graduate of Bellevue Hospital Medical College in 1867. He served as a medical cadet during the Civil War, and was the last cadet to be discharged in 1866.

Dr. D. L. Smythe, a graduate of the Memphis Hospital Medical College in 1901, died after a prolonged illness, at his home in Kosciusco, Miss., on February 10, aged 50 years.

Dr. Frederick Mathews, a graduate of the College of Physicians and Surgeons, New York, in 1882, visiting surgeon to the German Polyclinic Hospital, died at his home in New York on February 28, aged 58 years.

Dr. Henry Wilson, a non-practicing physician, City Manager of Newburgh, N. Y., died in that city on February 28, aged 54 years.

Dr. Bromwell Andrew, who had practised for twenty years in Jersey City, but now retired, was found dead in his residence in that city on February 25. He was 70 years old.

Dr. James Valentine Kern, a graduate of Cornell University Medical College, in 1902, died at his home in New York City on February 23.

Obituary.

THOMAS ADDIS EMMET, M.D., LL.D.,

NEW YORK CITY.

Dr. Thomas Addis Emmet, who died at his home in this city on March 1, was born in Charlottesville, Va., May 29, 1828, a son of Professor John Patten Emmet of the University of Virginia and a great nephew of Robert Emmet, the Irish patriot. He studied at St. Thomas' Hall in Flushing, L. I., and at the University of Virginia, and received his medical degree from Jefferson Medical College, Philadelphia, in 1850, soon thereafter entering upon practice in New York City. The following year he was appointed visiting physician to the Emigrant Refuge Hospital on Ward's Island. In 1885 he became assistant surgeon to the Woman's Hospital and in 1861 surgeon in chief, a position which he occupied until 1872. He was the author of a treatise entitled "The Principles and Practice of Gynecology" and also was a contributor on gynecological subjects to various medical periodicals. He was, during his active professional life, a member and often an officer of many local and national medical societies, particularly those devoted to obstetrics and gynecology. In addition to his many contributions to the medical literature, Dr. Emmet was one of the foremost collectors of American prints and autographs and extra-illustrated some 150 books. Dr. Emmet was an ardent advocate of Irish home rule, devoting much time to that cause throughout his busy professional life. In 1906 he was made a Knight Commander of St. Gregory the Great by Pope Pius X.

TIMOTHY MATLACK CHEESMAN, M.D.,

NEW YORK CITY.

Dr. T. M. Cheesman, who died at his home in Garrison-on-the-Hudson on February 25, was long prominent in the medical life of this city, but retired five years ago after suffering an attack of cerebral apoplexy. He was born in New York in 1853 and was graduated from the College of Physicians and Surgeons of Columbia University in 1878. After a period of internship in Bellevue Hospital, he began practice and was first appointed surgeon to the New York Dispensary and later physician to the Colored Home and Hospital and St. Andrew's Convalescent Hospital. He was at one time professor of bacteriology at Columbia University. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, the American Bacteriological Society, the American Society for the Advancement of Science, the New York Academy of Medicine, and the New York Pathological Society.

Correspondence.

A SQUARE LOOK AT COMPULSORY HEALTH INSURANCE AS PROPOSED IN NEW YORK STATE.

To the Editor of the Medical Record:

Sir:—The following estimates are based upon the Davenport-Donohue bill which is now before the New York Legislature and which has been endorsed by the New York State Federation of Labor with the object of "conserving human resources by establishing mutual health insurance funds under state supervision." This bill provides for all employees:

"Cash benefit of not more than $8 weekly during temporary sickness or accident disability not covered by workmen's compensation, such cash benefit to begin on the fourth day of disability.

"Medical and surgical treatment, supplies and nursing attendance for the insured employee and family, together with hospital or sanatorium treatment and maintenance, and dental care for the worker.

"Special maternity benefit for working mothers and wives of insured men.

"Burial benefit of $100."

The bill proposes an equal division of cost between workers and employers. All employees are to be insured without physical examination. The bill provides for free choice of physician and specifies that both medical and cash benefits shall be provided for a period of twenty-six weeks in any year.

The writer is in favor of the principle of compulsory health insurance for reasons which have been stated elsewhere; he believes that the medical provisions of the Davenport-Donohue bill can be greatly improved. The purpose of the present paper is not to consider arguments for or against health insurance or for or against the bill, but to take a square look at compulsory health insurance under the bill actually before the New York State Legislature.

Critics of this measure have stated that the enactment of such a bill would mean the ruination of the medical profession. The spokesmen of the American Federation of Labor have declared their belief that the worker's share of the cost of the proposed scheme will not in any case exceed 24 cents per week. The figures which follow, if measurably correct, show that if even the modest rates are allowed for professional service, there is little ground for believing either that the enactment of the Davenport-Donohue bill would involve the physicians of the State in financial ruin, or that adequate medical benefits can be provided for anything like the sum which the workers of the State have been told that they would be called upon to pay. Health insurance in New York State, under the law proposed, would necessitate, I believe, a volume of work and an expenditure per million insured persons (workers and dependents) approximately as follows:

ESTIMATE OF WORK AND COSTS PER MILLION INSURED

1.	1,000,000 x 9 days acute illness equals 9,000,000 days.	
2.	Hospital days, 300,000 at $2.50 per day (maintenance), for workers only	$750,000
3.	Hospital days, 300,000 at $1.00 (medical care).	300,000
4.	Hospital service (7,000 surgical operations at $25.00 each)	175,000
5.	Non-hospital days, 8,700,000; home visits, 4,350,000 at $1.00 per visit	4,350,000
6.	Non-hospital days includes 870,000 days of nursing care, at $4.00	3,480,000
7.	Office or dispensary visits, 3 per insured person (per annum) equals 3,000,000 at $.50	1,500,000
8.	Drugs and medical appliances, $2 00 per person per annum	2,000,000
9.	Maternity care, 21,000 home cases at $10.00	210,000
10.	Maternity care, 4,000 hospital cases at $25.00 for maintenance	100,000
11.	Maternity care, 4,000 hospital cases at $10.00 for medical care	40,000
12.	Dental care, $3.00 per worker	900,000
13.	Deaths, 15,000; 5,000 insured at $100	500,000
14.	Administration of Funds, 10,000 members to each fund; 100 funds at $15,000 each	1,500,000
15.	Cash benefits, 300,000 workers at $10	3,000 000
16.	State expenses (administration) ¼ of $480,000	60,000
17.	Various items (consultations, laboratory expenses, *x*-ray examination, special treatments, anesthesia, cash maternity benefit, dispensary charges apart from physicians' fees)	1,635,000
18	Contingencies	500,000
		$21,000,000

Comment.—1. Many estimates of the number of days of sickness under health insurance have been made. Rubinow says that "an average of ten days seems quite conservative and safe."

2. Payment is here assumed for all hospital service, but service of ward grade only is allowed for. Fees for special or individual nursing, in some cases, would have to come out of the sum allotted for nursing care (6). For other hospital "extras" see "Various Items" (17).

3. See note under 5.

4. Out of 14,000 or 15,000 hospital cases per annum there would not be less than 7,000 operative cases.

5. An estimate of 4,350,000 home visits for 8,700,000 sick days is believed to be reasonable. In many instances two or more sick persons would be seen during one visit; and daily home visits during incapacity are not always necessary. The amount of "$1 per visit" is not suggested as proper compensation, but is adopted solely for convenience in computation. To clarify discussion, the system is worked out on this basis. No special allowance is made here for consultations with specialists nor for any form of group or cooperative practice, nor for dispensary maintenance, nor for *x*-ray or laboratory work; these are covered under "Various Items" (No. 17). According to Rubinow, Leipzig reports only six office visits and two-thirds of a home visit per insured person per annum, or eight office calls and two home visits with the entire family covered. American families will hardly content themselves with this kind of medical attendance. At the rate of a visit every second day during incapacitating sickness it will require, say, 10,000 panel physicians in New York State to make 34,800,000 home visits per annum; each physician would make 3,480 home visits (average).

6. This might take the form of full nursing for one case in ten, or for one day in ten, or for part time or visiting nursing widely distributed. The rate suggested is less than that charged to-day by registered nurses in New York City, but some of this service would be rendered by attendants, whose legal recognition and regulation has recently been proposed by the registered nurses themselves.

7. About eight hospital, home, and office visits combined are allowed for each insured person (worker and dependents). This is above the number of visits reported by many British panel physicians working under the capitation system. The British records, however, do not include hospital or dispensary service.

8. The suggested allowance is somewhat greater than actual expenditures for these purposes abroad.

9. A birth rate of 25 per 1,000 is issumed.

10. It is estimated that one maternity case out of six might reasonably claim hospital care, either for medical reasons or on account of unfavorable home conditions.

11. The rate of $10 per case is presented as a basis for discussion. Many of the maternity cases that would be cared for under compulsory health insurance, especially in New York State, are today receiving hospital treatment gratuitously; on the other hand, some are paying more than the sum named in the schedule.

12. Dental treatment would presumably be limited to necessary extractions and fillings, and is promised only to workers (not to dependents).

13. Estimated death rate, 15 per 1,000. This is slightly above the death rate in the State, but is probably a fair estimate for the industrial group.

14. Includes salaries of lay officials and medical officer of the fund, office expenses, and the cost of official investigations. The Leipzig funds devote to administration about 8.6 per cent. of their total expenditures. This is a larger percentage, but represents a smaller sum than the 7.4 allotted in the present estimate.

15. Includes cash allowances to workers and to dependents of hospitalized workers.

16. Taxes in New York State will be increased not only by the cost of administration, but by about $5,000,000, representing the employers' contribution for 170 000 civic employees.

17. The estimate for these purposes is low; foreign experience is useless as a guide in relation to these items.

18. This item is intended to cover any expense not specifically provided, as well as all deficiencies in classified expenditures.

ADDENDA.

a. Estimated annual expense for New York State, $168,000,000. This includes no allowance for hospital or sanatorium construction.

b. The individual worker's contribution would be $28 per annum; the employer's contribution for each person employed would be the same.

c. Classification of payees:

		Per cent. of total payments.	Compare with Leipzig, 1917. Per cent.
To insured persons, cash benefits....	$3,000,000	14.3	45.1
To hospitals	850,000	4.	9.6
To physicians (midwives included).	6,575,000	31.3	23.5
To dentists	900,000	4.3	...
To nurses	3,480,000	16.6	...
To druggists and appliance makers.	2,000,000	9.5	11.
To undertakers	500,000	2.4	2.2
To officials (lay and medical).....	1,560,000	7.4	8.6
Various items	1,635,000	7.8	...
Contingencies	500,000	2.4	...
	$21,000,000	100.	100.

d. On the estimated basis of $1 per home visit and 50 cents per office visit, the total income of 10,000 physicians working as panel physicians in New York State, from health insurance sources only, would be $52,600,000, or $5,260 for each physician. To this add fees for consultations and special treatment. These figures are stated merely as an aid to the funds and the physicians in negotiating for suitable rates. It will be helpful to compare them with English figures. In order to facilitate the comparison, let us imagine that the work to be done will be distributed uniformly among the entire group of 10,000 physicians, representing two-thirds of the physicians practising in the State (with free choice of physician granted, there will, of course, be no such even distribution of panel practice). Each physician would then care for 800 insured persons (workers and dependents), and his annual income from the funds would be equivalent to a flat capitation allowance of $6.57, or about 27 shillings per person. In England physicians are today *asking* for 10 shillings and are receiving considerably less; but medical benefits in England do not include hospital care, and, apart from this, England has always had a smaller number of physicians relative to the population, and the people are not accustomed to as much medical attention as the people of this country demand.

e. Workers in New York State are today receiving gratuitously from public or private hospitals maintenance costing about $10,000,000 per annum and medical services (calculated at rates in this schedule) worth not less than $12,000,000 per annum.

S. S. Goldwater, M.D.,
Director Mount Sinai Hospital.

New York.

CONFERENCE ON REHABILITATION OF THE DISABLED.

To the Editor of the Medical Record:

Sir:—I should like to call to the attention of your readers a conference on the rehabilitation of the disabled which is to be held in New York City from March 18 to March 22 inclusive. This conference, which will be international in its representation and the scope of subjects to be discussed, should have a special interest for the members of the medical profession, and for all those who play a part in the restoration of the disabled to the best possible physical condition. The experience of America and that of the allied governments in occupational therapy, functional restoration, the fitting of artificial limbs, compensation, vocational reeducation, and kindred subjects, will be reported upon by experts in those fields.

The conference will be held under the auspices of the Red Cross Institute for Crippled and Disabled Men, and that part of the program related to the work for blinded soldiers will be directed by the Red Cross Institute for the Blind. Two of the evening meetings will be held in Carnegie Hall and will be open to the public. Representatives of practically all the governmental agencies in the allied countries dealing with disabled soldiers will attend, acceptances having already been received. Among the authorities to be represented are the British Ministry of Pensions, the French National Institute for War Cripples, the Belgian Military Institute for Crippled Soldiers, the Italian Ministry of Pensions, the Canadian Invalided Soldiers Commission, the Australian Department of Repatriation, and the Bureau of Reeducation and Reconstruction of the American Red Cross in Paris, in addition to other individual organizations in the respective countries.

Among the authorities in the United States which have promised representation are the Federal Board for Vocational Education, which is providing for American disabled soldiers training for self-support; the Division of Physical Reconstruction of the Office of the Surgeon General of the Army, which is providing restorative treatment and education during the convalescent period; the Bureau of War Risk Insurance, which furnishes artificial limbs to amputated soldiers of the American Expeditionary Force, and pays disability compensation; and the American Red Cross Department of Civilian Relief, which, through its home service section, provides social after-care for disabled men.

The gathering will be unofficial in the governmental sense, but scientifically of great authority, as many of the leaders in the rehabilitation work abroad will come to the United States for the first time to attend its sessions. Their presence here will afford opportunity to American workers in the same field to draw upon the experience of the foreign delegates for the solution of local problems.

While activities in behalf of the disabled soldier will figure largely in the program of both popular and scientific sessions, the interests of the disabled industrial worker will come in for a considerable share of attention. The invitations to the conference designate it as a "conference on the rehabilitation of the disabled man," civilian as well as military. Although the concentration of interest on the injured soldier has been responsible for the revolutionary change in national policies toward the disabled—whereby chief dependence is placed no longer on pensions but rather on the training of men to earn their own living—it is being generally recognized that many more men are disabled annually in industry than have been incapacitated by military service. It is the present aim of authorities having an interest in the cripple in general to apply to the treatment of the disabled civilian the same methods as have been developed to meet the needs of the invalided soldier.

One of the aims of the conference will be to direct public attention to the economy of putting disabled men back on the pay roll rather than permitting them to exist in idleness, supported by war pension or workmen's compensation. The plans of the various allied governments for the supply of artificial limbs to amputated soldiers is one of the subjects slated for consideration. The advantages of the adoption of a standard type of leg and arm will be reported upon in detail.

Douglas C. McMurtrie,
Director American Red Cross Institute for Crippled and Disabled Men.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 6, 1919.

The Medical Profession and Trades Union Tactics.—A curious meeting of the medical profession took place at the Wigmore Hall, Wigmore Street, London, on Sunday last. The Wigmore Hall is the great music salon which used to be attached to the business premises of Bechstein, the well-known piano manufacturers; and at the Bechstein Hall, as it then was called, some of the best modern music was regularly given to large audiences. The Bechstein Hall, now known under its British name, is situated in the very heart of consulting London, crossing the bottoms of Harley, Wimpole, and Welbeck Streets, and joining Cavendish Square and Cavendish Place with Portman Square. It is, therefore, an ideal place to hold a meeting of the medical profession, from the point of view of the convenience of the heads of that profession; but when a mass meeting is called at the Wigmore Hall it must be conceded that outlying medical men do not find the *locale* particularly convenient, while for the provinces it has the objection that it is not adjacent to any railway terminus. The meeting had its origin in the very natural feeling of anxiety as to what the prospects of the medical profession were to be under the new Ministry of Health. The questions at the bottom of professional unrest are something like the following: Will a State Service of Medicine be constituted under the Ministry of Health, and, if so, what will be the prospects of the general practitioner? Will the obvious State Services (that is to say, the medical services of the Local Government Board, the Board of Education, the Foreign Office, the Statistical Bureau at Somerset House, and so on) be coordinated into one homogeneous service, leaving the hospitals and their medical officers on one side and the general practitioners of the country on the other, free to pursue individual careers? Or will the State Service also undertake to nationalize the hospitals and affiliate general practice to the nationalized hospitals? In the case of the State taking part in the direct conduct and payment of the medical profession as a whole, what guarantees have the medical profession that the conditions of service and the payment thereof will be satisfactory? This is where, particularly, the shoe pinches, because, under the National Insurance Act, a third of the medical profession in England and Scotland, comprising probably more than half the general practitioners of these districts, did become, as panel doctors, more or less State servants, and have not expressed themselves universally satisfied with their new plight. Some general practitioners frankly own that their incomes are larger and more secure than they ever were under the old club system, where every man dispensed his own charity and selected for himself what cases he would see at low rates. Other medical men declare that as medical officers to their own clubs, choosing their own patients with some regard as to who should and who should not be an object of charity, their lives were easier and their balance sheets handsomer. These two divisions of general practitioners are in sharp opposition on matters of fact. The position of the British Medical Association somewhat complicates matters. The Association represents one-half of the medical practitioners of the country, and includes within that half men of all ways of thinking, though for the most part those who are opposed to panel practice are opposed to the policy of the Association, which at the time of the passing of the act made panel practice a possibility.

The meeting at Wigmore Hall was primarily called by practitioners opposed to panel practice, but it was made the occasion of a general debate, with all the circumstances just sketched present to the minds of the speakers. There were two resolutions only, and the first ran as follows: "In view of the prospective legislation and the proposed establishment of a Ministry of Health, and having regard to the experience of the medical profession at the time of the passing of the National Insurance Acts, the time has arrived when a body representative of the whole profession should be established to watch its interests and be prepared to act in an advisory capacity as occasion demands."

This resolution was powerfully opposed, not by any amendment, but by a demand for a directly contrary vote, the demand coming from the British Medical Association. The representatives of the association declared that in the association exactly such a representative body could be found, and that it would be waste of time to institute a new representative body, the better policy being for all medical men to sink their differences, and, by joining the British Medical Association, make it the center from whence the common decisions of the profession would emerge. Most of the speeches were destructive of the claim of the British Medical Association to be representative, and in the end the resolution was carried by 182 votes to 93.

A second resolution was then proposed in the following terms: "That a provisional committee be now formed with the object of securing the election of such a body," and, having been duly seconded, was made the subject of two directly varying amendments. The first amendment ran as follows: "That the meeting of the medical profession, in view of the urgency arising from contemplated legislation, approves the recognition of the Medical Parliamentary Committee as the provisional committee to be entrusted with the task of drawing up the constitution of a body to develop along the lines indicated by the first resolution."

This amendment received considerable support, but on going to division was negatived by 105 to 87. The weak spot in the advocacy of the Parliamentary Medical Committee was that that committee had had a non-democratic origin, while the avowed object of the meeting was to institute a body which should be representative on democratic lines of every shade of opinion and feeling in the profession. The Medical Parliamentary Committee has come far nearer representing all shades of opinion than any other body that has ever been created within the profession, but its constitution was criticised from the beginning as though it were a self-selected body. The criticism is not fair, because the meeting which called the committee into being had originally the support of the British Medical Association, as well as numerous other medical bodies, the representatives of those bodies being them-

selves for the most part members of the Royal Colleges. The authorities of the Royal Colleges, however, stood aloof, and later on the British Medical Association took up a policy of frank opposition to the Medical Parliamentary Committee, on the ground that that committee was trespassing on the domain which had already been chalked out for its own activities by the association. Those advocating the adoption of the Medical Parliamentary Committee as just such a body as was postulated by the first resolution, admitted that the committee was not yet representative, but gave to the audience good reasons for supposing that amendments in all the desired directions could be achieved and would be welcomed. The probability is that the amendment would have met with success if it had come on earlier in the afternoon, but the proceedings were very lengthy, and tea time was passed before the voting was taken. It was cynically suggested that the Wigmore Hall was in close juxtaposition to the houses of many practitioners who would inevitably have voted for the amendment, but that the call of tea proved too strong for them.

After the failure of an amendment proposing to erect the Medical Parliamentary Committee into a representative body of the profession a second amendment to the second resolution was proposed in the following terms: "That in the opinion of this meeting no committee or organization is capable of effectively representing the interests of the profession unless it is a registered medical trade union."

This resolution was supported by some extraordinarily vigorous speaking, in the course of which it was pointed out that the most effective weapon of the trades union is the strike, and that no medical man could contemplate with equanimity the public circumstances in the event of a medical strike. Even this, however, was contradicted by one section of the meeting, who replied with a whole-hearted determination to strike should that be the only way to obtain the terms which they considered just. The second amendment to the second resolution was lost by 2 votes, the numbers being 73 to 71, when the losers immediately insisted upon a recount. This placed the chairman of the meeting in an embarrassing situation, because already some who had voted had left the hall. He came to the decision—which was strongly supported by many in the room—that the recount would be impossible. But the losers of the amendment refused to pay any attention to his ruling as chairman, whereupon the meeting broke up in disorder. If the object of the meeting was to impress the Government, now on the point of initiating medical legislation, that the medical profession would be unanimous on state questions, the object failed in a lamentable manner. The meeting by a substantial majority declared itself in favor of the institution of a representative body, but failed to pass a second resolution defining that body.

An Attempt at Unanimity.—In view of the failure to achieve unanimity at the Wigmore Hall meeting, the following story is not without its point. Two eminent alienists met, and found that they were both called to give expert evidence in the same case and on the same side. The elder inquired what fee the younger was going to charge, when the reply was "Forty guineas." "I shall charge fifty," replied the senior man. They met some days after the hearing of the case, when the elder man said: "I took your advice, and charged forty." To which the junior responded: "And I took yours, and charged fifty." Medical unanimity on any point is difficult to obtain.

The Extension of Institutional Facilities for Medical and Surgical Treatment.—Up to a comparatively recent time the provision of treatment for those who could not afford to pay private practitioners was left to the Poor Law authorities and to the voluntary efforts of the charitable. Under these latter efforts have arisen the excellent general and special hospitals which now adorn every city in the United Kingdom. Lately these voluntary hospitals have had very respectable rivals in the infirmaries attached to the workhouses and under the ægis of the Poor-Law Guardians. Not so very long ago these infirmaries, being the sick-bay of the workhouses, as sailors would have called them, were simply filled with helpless, senile, chronic cases, many of them on the verge of imbecility, and most of them awaiting a death that would be merciful to themselves and economical to the State. But the character of these institutions and the work done in them have radically changed of late, and in the admirable buildings recently provided by the Poor Law Guardians clinical treatment of the highest sort is carried out. But the facilities for institutional treatment are inadequately distributed, nor do they provide in a general way for the needs of the community. Reform has not yet gone far enough, and this is the more regrettable in that the position is particularly acute at the present moment owing to the large number of sick soldiers returning for demobilization.

The Strike of Railway Men.—London has been severely inconvenienced this week by the closing of the tube and district railways owing to the strike of a group of the drivers. The strike is said to have been sympathetic in origin; that is to say, it was not due to personal grievances in London, but to the fact that alleged grievances in Glasgow have not been redressed. It is the working men of London whom this group of working men has treated most cruelly by compelling some of them to walk ten, and many thousands of them to walk five miles, to their work. The weather, it happens, has been singularly atrocious, severe frosts being followed by southeast winds, snow, sleet, and fog. Through the cold steaming mist, ankle deep in congealing slush, thousands upon thousands of London working men and women have been compelled to tramp morning and night for hours before beginning and after ending their work, and it is inevitable that the labor and exposure should tell upon them. It is a bad start for the day to be tired and wet through, but it is particularly dangerous for hard-worked people to walk miles after the day's toil is over, and from a medical point of view the strikers have assumed a heavy responsibility.

Medical Men in Parliament.—Parliament began to sit yesterday, and 11 medical men will find a place there during the coming sesssion. Sixteen medical men were elected to Parliament out of 37 who were candidates, but 5 of the successful men were Sinn Feiners, and will presumably not take

their seats. Medicine comes off very badly in comparison with law, for there are 92 members of the legal profession in the new Parliament. The proportion will have to be altered in the near future. A plethora of lawyers has been submitted to hitherto on the ground that they ought to be the best people to handle laws; it is now seen that the motive behind the measure is immeasurably more important than its details, and that preventive medicine is going to be the grand motive force of enlightened statutes.

The Closure of the Belgian Doctors' and Pharmacists' Relief Fund.—At the last meeting of the executive committee of this fund a letter was received by the committee from Dr. V. Pechère, the president of the Comité National de Secours et d'Alimentation. This national committee is the body sitting in Brussels to which the dispensation of the contributions of the funds in behalf of the suffering Belgian doctors and pharmacists in Belgium has been entrusted. The Belgian Doctors' and Pharmacists' Relief Fund has raised upward of £25,000 during its life of a little over four years. The greater part of this money has been received directly from British doctors and pharmacists at home, in the colonies, and in India, though during the closing stages of the war substantial grants have come from the American Red Cross, to the enormous benefit of the charges of the fund. After the immediate wants of Belgian doctors and pharmacists and their families arriving in this country as refugees had been met by the fund the bulk of the money was duly distributed in monthly donations varying from £800 to £400, among Belgian doctors and pharmacists remaining in Belgium, the organization of which Dr. Pechère is the head undertaking the difficult and delicate task of distribution. Dr. Pechère's committee has wisely husbanded the contributions sent to them, so that a certain amount of money should remain in hand for the succor and rehabilitation of Belgian doctors and pharmacists after the war; and it goes without saying that the extraordinarily generous suggestion of Dr. Pechère, which will be found in his eloquent letter of gratitude—that this money should be returned to the fund—has been disregarded by the committee of the fund. It was definitely stated in the original program of those who organized the fund that it would be impossible for British doctors and pharmacists to give too much money, because when the immediate needs had been met those of rehabilitation must remain, and be very heavy. Many doctors and pharmacists in Belgium were materially ruined, and would not be able to return to work without pecuniary grants. All readers of the medical and pharmaceutical journals who have kept the objects of the fund in recollection will approve of the decision of the committee of the fund.

The Belgian Doctors' and Pharmacists' Relief Fund is closed as from Monday next, February 10, the small sum remaining in the hands of the honorary treasurer being probably sufficient to meet any remaing calls from Belgian refugees in this country. The fund has disbursed the whole of the sum collected—over £25,000—save £90; and the cost of collection and distribution has been under £200, including the printing and postage of circulars and reports at war rates. The secretarial work and that of the treasurer have been done gratuitously both by the officers named and by their assistants; a large proportion of the postage has been defrayed by *The Lancet;* the auditors made their inspections of and reports on the books of the fund for a nominal fee; and the bank treated the fund with special courtesy. These are the things that account for the economical administration of the fund's resources.

2. Psychic Hydrophobia.—John D. Quackenbos points out that apart from the hydrophobia associated with rabies, this condition may be a true phobia of purely psychic nature and origin, taking class with mysophobia, acrophobia, and agoraphobia, and is to be further distinguished from hydrophobophobia, or morbid dread of hydrophobia as transmitted by rabid brutes. He reports the case of a woman in whom, as in rabies, a spasm of the pharyngeal constrictors and muscles of the larynx suddenly occurred, closing the epiglottis with a strangling sensation. The first attack was precipitated by her marriage to a man she detested and occurred as she stood before the altar. Gradually a difficulty in swallowing developed; the spasm returned with every attempt to quench her thirst, and finally at the very thought or sight of water. When seen by the author, she was accustomed to occupy four hours every morning fighting with the water in the basin to get her face washed, and an effort to force a teaspoonful of water into her stomach was accompanied by an agonizing struggle to drive air through the constricted larynx into her lungs. An extension of the obsessive idea terminated in the delusional conviction that there was water in everything she ate or touched, and she spent hours in wiping articles of food and chinaware to remove suspected moisture therefrom. The suffering connected with the use of water had become so intense that she had lapsed into a state of melancholia and prayed for death. The patient was put into a receptive sleep and cogent destructive suggestions were given. After the second treatment she called eagerly for water, of which she drank nine tumblerfuls; the backbone of the phobia was broken. The author reports other cases of a similar nature: That of a youth of twenty-five who had witnessed a drowning accident. In this case there was no difficulty in swallowing water but an aversion to entering it, so that it became impossible for him to take a bath. Another case was that of a college instructor in athletics who became obsessed after a cat scratch with the belief that he had hydrophobia. It transpired that his mother before his birth was tortured with a fear that a dog would bite her and his susceptibility to the specific idea was hereditary. A further case quoted was that of a professional man. One of his foxhounds ran mad through his pastures, whereupon he developed an obsession and a horror of salivary pollution. He refused to drink the milk of his cows for fear it had been contaminated by saliva from the mouth of the rabid dog; he would burn clothing, furniture, books, and even valuable papers for fear they had been touched by the dog's spittle. In all these cases a cure was effected by means of psychotherapy coupled with persistent elimination of toxins and supplemented by forced feeding for the impoverished cells. This, in the author's opinion, is the only rational means of treatment.

7. A New Treatment for the Morphine Habit.—C. S. Bluemel reports the results obtained in two series of cases of morphine addicts treated by intravenous infusions of physiologic sodium chloride solution. The method was suggested to him by the fact that elimination appears to be nature's way of counteracting the drug, as evidenced by the withdrawal symptoms of sweating, vomiting, and diarrhea, and, moreover, plays an important part in the methods of treatment usually followed. It appeared to him that the process of elimination could be greatly augmented by the administration of intravenous infusions, for the solution would be eliminated by the kidneys and intestine and should carry the toxines with it; furthermore, the toxines of the blood stream would be diluted. These theoretical considerations led him to attempt the treatment of chronic morphinism solely by elimination, supplementing a catharsis of the intestinal tract with a catharsis of the blood stream brought about by repeated intravenous infusions. The patient was put to bed and morphine stopped entirely. He was put on a semisolid or liquid diet and given cathartics as prescribed in the Towns-Lambert treatment, receiving three or four courses consisting of five grains of blue mass with five compound cathartic pills at intervals of approximately 18 hours. Some hours after the last of these courses castor oil is given. The patient receives from two to four intravenous infusions a day, according to his condition, the standard infusion consisting of 1000 c.c. of 0.9 per cent. sodium chloride in sterile freshly distilled water. During the first few days of treatment about 30 grains of chloral is given at bedtime to ensure a night's rest. Hypnotics are an important element in the treatment for they insure rest and the sleep they induce blots out large periods of discomfort; moreover, they fortify the patient mentally and physically. Patient is kept in bed until all acute discomfort from the withdrawal of the morphine has ceased. Should he complain unduly of withdrawal symptoms, a saline infusion is given. No harmful effects have been observed from the administration of saline infusions; on the other hand, the condition of patients has improved. In one case infusions amounting to 50 per cent. of patient's body weight were given in thirteen days and resulted in great improvement in the physical condition. The procedure does not produce marked increase of arterial tension or anemia—there is slight decrease in the red cell count and in the hemoglobin owing to the increase of the fluid element of the blood, but no destruction of cells. There is marked decrease in the viscosity of the blood which lessens capillary resistance and reduces the normal heart load. This in turn reduces the tendency to heart weakness and permits of the administration of large doses of chloral. Cardiac stimulants were not found necessary in any of the cases under consideration. Of the six patients so treated, the average age was 34, average period of addiction was 12 years, and the average daily dose of morphine taken 7 or 8 grains. Three used cocaine occasionally, and three had positive Wassermanns. The average length of stay in the sanatorium was 14 days and the average amount of saline administered to each patient was 15,600 c.c. Discomfort was experienced for two or three days but was not marked at any time. A period of nervousness and sleeplessness followed but, as a rule, hypnotics were taken only for four nights. During this period of restlessness two patients who had been addicts for more than twenty years were given the Towns-Lambert treatment without morphine. The nervousness diminished considerably and their improvement seemed to point to some specific potency in the belladonna mixture which forms part of this treatment. The author, however, is inclined to attribute the success in part to suggestion, since the Towns-Lambert was known as an accredited treatment to the patients whereas the infusions were known to be simply experimental. A second series of six cases was then given the Towns-Lambert treatment (with the gradually decreasing doses of morphine) together with the infusions. In this series the cases were milder than in the former cases; the average age was 40, the average period of addiction 9 years, and the average daily dose of morphine previously taken 3½ grains. Four of these patients occasionally used cocaine and three had positive Wassermanns. The first two patients received infusions only when they manifested discomfort under the Towns-Lambert treatment; the remaining four received them from the commencement of treatment. On the average five infusions were given and as a rule they were not continued beyond the third or fourth day. The average day of discharge was the seventh. In this series the discomfort suffered was about the same as in the former series in which no morphine was given, but the patients recovered more rapidly from the subsequent period of nervousness. It would appear, therefore, that the combined treatment is superior to the infusion treatment alone, but in order to determine this satisfactorily two equivalent series of cases would have to be compared. The authors give a report of each case in each of the series. Commenting on morphinism in general, they suggest that since 75 per cent. of addicts are the result of careless administration of morphine on the part of physicians and are therefore by-products from the practice of the medical profession, and the majority of the remaining 25 per cent. owe their habit largely to government negligence, they are entitled to a square deal. The Harrison Narcotic Drug Act, in 1915, automatically stopped the available supply of morphine but did not stop the physiological need of the morphinist, simply throwing him into the hands of the illicit dealer. It would seem, therefore, that the least that could be done would be to license the addict. It would be still better to cure him, however.

3. Preliminary Report on the Presence of a Filter-passing Virus in Certain Diseases, with Especial Reference to Trench Fever, Influenza, and Nephritis.—Major General Sir John Rose Bradford, Captain E. F. Bashford, and Captain J. A. Wilson, as a result of observations on the pathology of acute infective polyneuritis, carried out during the autumn of 1917 and the spring and summer of 1918, succeeded in isolating an organism that reproduced the disease when inoculated into animals, and, further, was recovered by culture, by the Noguchi method, from such experimental animals. Full details of the work will be published in the *Quarterly Journal of Medicine*. The organism isolated belongs to the group known as "filter-passers", in that the virus

will pass through certain filters but does not pass through those with very fine pores. In view of the satisfactory results obtained in the study of polyneuritis, an investigation was undertaken into the cause of other diseases, particularly trench fever, influenza, and nephritis. In trench fever the virus isolated consists of minute coccus-like bodies, grouped in pairs, with the opposing surfaces flattened, and varying in size from 0.3 μ to 0.5 μ. It is Gram-positive and stains readily if the film preparations are first washed in ether. It passes through Berkefeld N. and V. filters and through Massen porcelain filters, and can be cultivated from such filtrates. It resists heating to a temperature of 56° C. for 30 minutes and it is an anaerobe. This organism has been recovered by culture from the blood in 11 out of 15 cases of trench fever examined during the pyretic stage, and in 3 out of 8 cases examined when apyretic. It was not found in over 40 control cases where blood culture with the same technique was carried out. A similar organism was recovered from four separate supplies of infected louse excreta, but it was not found in 31 specimens of excreta from batches of clean lice. The culture obtained either from the blood of man or from louse excreta, when inoculated by scarification into man, produces a mild illness, and the organism can be recovered from the blood by culture during such illness, and also from clean lice fed on the patient during the illness. The virus isolated in cases of influenza consists of very minute rounded coccus-like bodies, varying from 0.15 μ to 0.5 μ. It is Gram-positive and passes through Berkefeld N. and V. filters and Massen porcelain filter. It is an anaerobe, and resists heating to 56° C. for 30 minutes. It has been isolated by culture from the blood in 6 out of 9 cases examined, from the sputum in 6 out of 6 examined, from pleural fluid in 4 out of 4 examined, and from the cerebrospinal fluid in the only case so examined. It has also been isolated from the lymphatic glands post mortem in the only two cases examined. This organism cannot only be grown from the blood, and from exudates, but it can also be seen in stained films prepared from exudates, *e.g.* sputum, pleural fluid, cerebrospinal fluid. The culture (second generation) when inoculated into animals subdurally, or intravenously, produces illness in guinea-pigs and monkeys, and on post-mortem examination the following lesions have been found: extensive lobular pneumonia with hemorrhages, some nephritis, myocardial and hepatic lesions, such as extreme congestion, interstitial hemorrhages of small size, and fatty degeneration. Passage experiments done from such animals when slightly ill, by injecting their blood, bile, etc., into healthy animals, causes in these more severe and even fatal illness, and post mortem the same lesions are found. The organism has been recovered by culture from the tissues of such experimental animals. Up to January, 1919, only one variety of nephritis had been investigated, *i.e.* that characterized by the presence of pyrexia and hematuria at the onset. The virus isolated in such cases consists of a round coccus-like body varying from 0.3 μ to 0.6 μ in size, and in culture often occurring in the form of short chains of four individuals. The same organism may be seen in urinary sediments either singly or in pairs. It is Gram-positive and passes through Berkefeld N. and V. filters, and also through the Massen porcelain filter. It is an anaerobe and resists heating to 56° for 30 minutes. It has been isolated from the blood in 6 out of 9 cases examined and from the urine in 7 cases. The culture (second generation) when inoculated into animals produces nephritis in monkeys and guinea-pigs. In monkeys this can be determined not only by post-mortem examination, but also clinically, since the urine contains blood, albumin, and casts. In both guinea-pigs and monkeys extensive lesions, glomerular and tubular, are found on microscopic examination. In severe cases pulmonary lesions are also present. The organism has been recovered by culture from the tissues of the animals experimentally inoculated. Organisms of the same group, although differing from one another, have been isolated from a number of other diseases of obscure etiology, of which the more important are: mumps, measles, rose measles, and typhus. An organism apparently allied to that of polyneuritis has also been isolated from brain tissue in cases of encephalitis lethargica, both from material obtained in England and from cases observed in the Army in France. Excluding the organisms found in polyneuritis and encephalitis lethargica, all the organisms isolated have many points in common and possibly belong to one group. Although exceedingly small, they present individual differences in their morphology and in their mode of growth in culture. Details, however, will be published later.

1. A Clinical Study of Four Hundred Patients with Bronchial Asthma.—I. Chandler Walker discusses the protein causation of asthma and points out that proteins are most widely distributed in nature and that as patients may be sensitive or anaphylactic to proteins, these may be the cause of all varieties of asthma, including the bronchial variety. There are several ways of testing a patient in order to determine whether or not he may be sensitive to proteins. The test which has proven to be safe and reliable as regards hay fever and asthma is performed as follows: A number of small cuts, each about one-eighth of an inch long, are made on the flexor surfaces of the forearm. These cuts are made with a sharp scalpel, not deep enough to draw blood, although they do penetrate the skin. On each cut is placed a protein and to it is added a drop of tenth-normal sodium hydroxide solution to dissolve the protein and to permit of its rapid absorption. At the end of a half hour the proteins are washed off and the reactions are noted, always comparing the inoculated cuts with normal controls on which no protein has been placed. A positive reaction consists of a raised white elevation or urticarial wheal surrounding the cut. The smallest reaction which can be termed positive must measure 0.5 cm. in diameter, and any smaller reactions are called doubtful. Negative skin tests with proteins rule out these proteins as a cause of asthma, and all proteins which give a positive skin test should be suspected as a cause of asthma. In the case of bacteria, however, the skin test has only to do with the protein element, so that even though bacteria give a negative test they may still be a cause of asthma though their infectious nature and the patient need not be sensitized to bacterial protein. Of the 400 cases studied by Chandler, 191, or 48 per cent., gave a positive skin test, and were therefore sensitive to some protein. According to sex, 53 per cent. of the sensitive cases were males and 47 per cent. were females, and of the total number of males studied 51 per cent. were sensitive, and of the total number of females 44 per cent. were sensitive. The author also emphasizes the fact that the relationship between the age of onset of bronchial asthma and the sensitization of the individual is important. Stated briefly, four-fifths of the patients who began asthma during infancy were sensitive, two-thirds who began during childhood were sensitive; one-half of those beginning asthma during young adult life were sensitive, and none was sensitive that began asthma after the age of fifty; as the age of onset of asthma increases, the frequency of sensitization decreases, and the knowledge of this is a great help in practice. A positive skin test with several different proteins may mean that all of them are causing asthma or that only some of them are causing asthma at present, and that the others have been or may be in the future the cause; or even it may mean that none of the proteins is at present the cause, but they have been and that now secondary infection is the chief cause of asthma. Suffice it to say that positive skin tests by proteins, which seem to have no

hearing on the cause of asthma, should be considered as danger signals and not as false reactions; such positive tests should not be disregarded. The treatment of sensitive cases is largely a matter of judgment in deciding which positive tests should be first investigated. If the patient is sensitive to food proteins, such foods should be omitted from the patient's diet for at least a month in order to see what effect they have on the asthmatic condition. In Chandler's series of cases nearly all such patients have been relieved of asthma. In a few instances, however, because of the associated bronchitis, autogenous sputum vaccines have been required in conjunction with the restricted diet. Attempts to desensitize the patient against offending food protein by the subcutaneous injection of, or by feeding gradually increasing amounts of the protein have failed. There are, however, reasons for believing that total abstinence from the offending protein for a long interval automatically desensitizes the patient for that protein. Patients who are sensitive to bacterial proteins may be successfully desensitized against such by treatment with vaccines of these organisms, but great care must be exercised not to give too large and too rapid an increase in the amount of vaccine. The first dose of vaccine should not be larger than one hundred million bacteria, and each succeeding dose should not be more than fifty million over the preceding dose.

3. Administration of Arsenic in Syphilis.—Lockhart and Atkinson point out that the methods of administering the organic arsenic preparations are almost invariably of a too elaborate character. Moreover, the drug is too unstable to retain its therapeutic properties when given in the form of capsules to be administered per os or introduced into the rectum. The authors have adopted in their clinic at the Canadian Special Hospital, Whitley, England, the intravenous method of injecting arsenic introduced by Professor Thibierge. The method of administration is as follows: A 30 c.c. burette containing the sterile water is held upright by a stand and is continued at the bottom by a short piece of rubber tubing terminating in a glass nozzle and closed by a pinch cock. One of the orderlies flames the outside of an ampoule of the drug with a small alcohol lamp, files off the tapering end, runs in 2 c.c. of water from the burette and inserts a piece of small glass tubing with rubber connection at one end and a few filaments of wood at the construction near the center, such as is supplied with the galyl ampoules. The ampoule is then gently shaken. Solution is complete in a few seconds. The ampoule is placed upright in a small board which has had sufficient half-inch holes drilled in it to hold the required number of ampoules. The officer having picked a syringe out of a small basin of alcohol with dressing forceps, washes it in sterile saline solution, aspirates the contents of the ampoule by means of the rubber connection to the glass tube, picks out one of several needles which are boiling in a container beside him, and adjusts it to the syringe. Meanwhile the other orderly has prepared the patient by fastening a light rubber tube round his upper arm and painting below the bend of the elbow with iodine. The patient seats himself at a narrow table on the opposite side of the officer, his arm resting on the table, the officer steadying the skin with his left hand, introduces the needle into the vein, slightly withdraws the plunger to make certain that the needle is in the lumen of the vein, and, removing the tourniquet, completes the injection. The table should be so placed that the light falls freely on it. The needle puncture is so small that no bleeding takes place and no cotton or collodion is required to seal it. During the past three months 2,859 intravenous injections have been given in the above manner in the Whitley clinic. There has not been a solitary case of thrombosis of the vein. There have been no early reactions of an anaphylactic character such as used to be fairly frequent when injecting large quantities of distilled water, which was not above suspicion. There have been no reactions, late or early, which could be attributed to the method of administration. Owing to the small size of the needle the pain of introduction is less than where the larger needle required by the gravity apparatus is used, and much smaller veins may be successfully entered. A microscopic examination of blood withdrawn from the vein into the syringe containing the arsenic solution shows the blood cells apparently even some hours after withdrawal. The drugs used by the authors have been Novarsenobillon and Novarsenobenzol, which have been supplied in ampoules containing 0.6 gm. and 0.9 gm. It has seemed to the authors that the administration of arsenic in concentrated solution is more effective than when it is given diluted. It has been shown that intravenous arsenic as ordinarily administered is eliminated pretty rapidly by the kidneys so that a large part of the dose is disposed of in this way within a few hours after administration. The diuretic effect of the distilled water and saline solution introduced into the circulation along with the arsenic may have something to do with this, and it is reasonable to suppose that when the dose is given in concentrated form it is less rapidly eliminated. There are no means to estimate quantitatively the arsenic in the urine and therefore it has been impossible to verify the supposition. When arsenic is administered by a gravity apparatus it is customary, in large clinics, at any rate, to dissolve the doses for several patients at once, and as the solution is run out more is continuously added during the period of an hour or longer according to the number of patients. It is clear that in this way some portion of the drug will be exposed to the air for a considerable time, as the tube is never allowed to entirely empty itself, and some degree of oxidation is bound to occur. Where solution is effected in the ampoule immediately after it is opened and the contents injected within a minute or less, oxidation prior to administration must be very slight indeed. In default of support from estimation of the rapidity of arsenic exeretion it must be admitted that the number of cases is too few and the period of observation too short to establish the truth of the supposition that concentrated solution of arsenic is more effectual than dilute, but there is sufficient evidence to show that by their use syphilitic lesions undergo very rapid involution, and that their administration in suitable dosage is perfectly safe.

Berliner klinische Wochenschrift.

December 30, 1918.

Two Procedures of Cutaneous Plastic Work.—H. Neuhäuser describes, with figures, the following two techniques of plastic surgery for the repair of wound surfaces. The first consists in forming thin cutaneous flaps on the edges of the wound. They should be from six to ten centimeters long and pedunculated at one end. These are then brought over the wound surface and sutured. The advantage of this procedure resides in a very rapid epidermization on account of the considerable extent of the proliferating borders of the flaps. The second technique is more complicated and takes longer to carry out. For its understanding it requires to be illustrated, and consequently will not be described.

Radiotherapeutic Treatment of Local Hyperhidrosis with Hard Rays.—F. M. Meyer, after six years' work along these lines, believes that only hard radiations, greatly filtered, can surely cure hyperhidrosis. The dose of rays employed must vary with each case and it is well to proceed by repeated séances, each one of which should be made at a different area of the cutaneous surface under treatment. A cure requires considerable time, since destruction of the sudoriparous glands must be obtained. As to complications, an alopecia frequently results in the axilla and, besides, the skin offers a certain hardness with a tendency to fissuring. However, these untoward results are readily accepted by patients for the good results otherwise obtained.

Edema Disease and Bradycardia.—Bencke describes the well-known clinical picture of this affection, which results from inanition and excessive work. A diet of better quality, particularly richer in fats, will cause the symptoms to disappear rapidly.

Cutaneous Changes in the Nephritides.—G. Herxheimer and W. Roscher recall the fact that examination of the cutaneous vessels has been made recently

by a number of writers, either by direct visual examination or in serial histological sections, with the attempt to show that the changes found offer characteristic symptomatic evidence in various affections, such, for example, as trench nephritis, Weil's disease, recurrent typhus, Volhynia fever, etc. The writers have taken up this study and have been unable to discover that these various diseases can be differentiated by this means since the morbid changes in the vessels are practically identical in all and result from an ordinary inflammatory process. On the other hand, these changes have nothing in common with the characteristic lesions present in typhus fever as already described by Fraenkel. As to the identity of trench nephritis with typhus fever, it is absolutely refuted by the results of histological studies of the cutaneous vascular system.

Essays with Vaccination Against Typhus Fever.—H. da Rocha-Lima has utilized the well-known essential faculty possessed by the guinea-pig of becoming inoculated with typhus fever for the purpose of experimenting with vaccines of divers manufacture, such as the blood from patients, extracts of the viscera of diseased guinea-pigs, lice carriers of the virus, etc. The series of comparative experiments, with a control series, revealed the fact that a vaccine made from virulent lice was the most powerful. Repeated vaccinations, two to three being made during the lapse of one week, had a manifest immunizing effect, which a single vaccination did not possess. The writer's researches carried out in a considerable number of guinea-pigs showed a perfect innocuity of these subcutaneous injections of vaccine made from virulent lice and, according to his way of thinking, everything indicates that it should be employed in man. The only objection to the extensive use of this vaccine resides in the difficulty of procuring it in sufficient quantities. Therefore, the writer proposes to limit this vaccination for the time being to persons particularly exposed to contamination.

Results Obtained in Tuberculous Patients Treated in 1913 with Friedmann's Serum.—F. Kraus treated eighty-five tuberculous patients with Friedmann's injections (tubercle bacilli of cold-blooded animals) in 1913, the lesions representing all degrees of the disease. After the lapse of five years (1918) the writer was able to examine twenty-five of these patients and found that, all things considered, the results were good. As to the remaining patients, the majority gave favorable data as to their condition by letter. As all these cases treated by the writer offered undoubted clinical evidence of tuberculosis in 1913, Kraus does not hesitate to recommend Friedmann's treatment on a large scale.

Psychic Disturbances During Influenza.—Weber records several cases of acute psychoses arising during defervescence or even during convalescence from the grippe. They were delirious states with motor agitation, hallucinations, obnubilation, etc. The evolution was completed within from four to ten days and the prognosis was good.

The Technique of Treatment with Silver-Salvarsan.—Mock has observed vasomotor disturbances in some cases following the use of silver-salvarsan, although such complications are uncommon. In sensitive subjects the writer consequently substitutes intravenous injections by diluted solutions, slowly injected subcutaneously, the dose being 200 c.c.

December 14, 1918.

Bullet Wounds of the Optic Tract.—V. Hanke records two cases, one of which particularly represents a typical lesion with right homonymous hemianopsia. As to symptoms belonging to the localization in the optic tractus the writer gives: integrity of the macula, hemiopsic papillary reaction, and inequality of the pupils, the larger pupil being on the side of the hemianopsia.

The Potato Cure in Cardiac Hydropsy.—I. Lipiner states that, on account of the general dearth in all things resulting from the war, he has been led to substitute a diet more readily realizable for Karell's treatment. For this the writer has resorted to the potato cure, the effects of which have been excellent. After a lengthy dissertation on the means of diuresis, the duration of the disease, and the loss of weight, the writer shows the superiority of the potato cure over the diet recommended by Karell, as well as its usefulness in case of intolerance for digitalis, also its superiority, when carried out alone, over the treatment by rest and digitalis when given alone.

Influenza in Animals.—Lanfranchi considers this subject informally. A contemporary writer has stated that an epizootic has coexisted with an epidemic on five occasions without any claim that this number exhausts the list. Our exact knowledge of equine influenza does not go back very far owing to the backward state of scientific veterinary knowledge. Two independent observers in 1911 and 1913 were able to show that the affection is due to a filtrable virus and that apparently healthy animals act as carriers. This discovery abundantly explains the observations of prescientific veterinaries that influenza was conveyed to mares by the semen of the stallions. The theory of a filtrable virus as a cause of human influenza has therefore a sort of indirect corroboration. A sort of nasal infection in young dogs wrongly termed glanders has numerous analogies with influenza and extends down the respiratory tract. Only exceptionally does this become epizootic and then its correspondence with human influenza is very close. It is shown to be due to a filtrable virus. In hog cholera we see numerous analogies with influenza. There is a nasal catarrh accompanying the fever, although generally speaking all of the mucosae may suffer. There is a virulent septic form which can destroy the animal in a few days. The actual cause of the disease is a filtrable virus while complications arise from the pathogenicity of satellite germs.

The Hospital St. Louis.—Jeanselme devoted the opening lecture of the university course for the chair of skin diseases and syphilis to the history and activities of the clinic in question. He does not go very deeply into the past, although all the world should know that this institution anticipated all others of its kind in dealing with these cases. In syphilography he does not go before the activities of Fournier, who went from the Lourcine to the St. Louis many years ago and most of whose original research was performed at the latter institute. Fournier devoted twenty years of his life to the St. Louis and was succeeded by Gaucher, whose work is described at length. The author now takes up the succession of remarkable dermatologists who have shed luster on the St. Louis and begins with Alibert, whose teachings were continued by Biett and Cazenave. But an event of minor importance, which ultimately redounded to the credit of the hospital, yet was not connected with the activities of any clinician, was the discovery by the apothecary Gales that itch was the result of the parasitism of a tick, the acarus. Naturally Gales was ridiculed by the humoralists of the day, until in 1834 Renucci, a student, succeeded in convincing the great Alibert of the truth of the assertion. During the period 1841-44 Gruby, who made his researches in the hospital, demonstrated the analogous part played by fungi in disease of the scalp. Bazin, who assumed charge of the hospital in 1850, was a progressive type of man, who endorsed all of the alleged discoveries of the past, supported by an improved microscopic technique. Later the prestige of the St. Louis suffered an eclipse as a result of the labors of the Vienna School, which upset much of the Paris doctrine of diathesis as a cause of skin lesions. The somewhat ultrascientific movement in Vienna was met by the germane activities of French dermatologists, who followed scientific methods to the utmost. Since then there has been but one school of dermatology.

Stated Meeting, Held April 23, 1918.

DR. WILBUR WARD IN THE CHAIR.

Large Pelvic Abscess Due to Foreign Body in the Posterior Vaginal Wall.—Dr. WILBUR WARD reported this case which illustrated another danger in the use of the stem pessary. He stated that the patient, a widow in the early thirties, consulted him in the absence of her own physician as she had been wearing a stem pessary for some time for the relief of dysmenorrhea, this being so severe that she was confined to bed for two days each month. With the pessary in place no discomfort whatever was experienced. Her physician had been in the habit of leaving the stem in for six months, then removing, cleansing, and replacing it. Her visit to the speaker was for this purpose. While he did not approve of the use of the pessary, he did not feel it incumbent upon him to say so, and treated the patient as she had been accustomed to being treated. Three years later, a stewardess of one of the coastline steamships called him up and said that she had on board a woman who was quite ill, who said that her physician was out of town, and that Dr. Ward was the only other physician she knew. From what the stewardess said it seemed that the condition was medical, the patient in common with a considerable number of the passengers suffering from nausea, vomiting, abdominal pain, and diarrhea, all of the cases being laid to the ingestion of some tainted food. Inasmuch as the cases did not seem to lie within his province he recommended the patient to an internist, who in the course of the next 36 hours sent her to a private room in one of our large hospitals, and put her under medical treatment. Seven days later the house surgeon called him up and said the condition seemed to be pelvic, and asked him to come to see her. He did so and found that for a week she had been treated along medical lines without a diagnosis having been arrived at. She was running a gradually increasing septic temperature, looked ill, and that morning they had first discovered a mass rising out of the pelvis, and appearing above the symphysis. He had the patient transferred to the Sloane Hospital and in making a complete vaginal examination the first thing he encountered was the collar of a stem pessary which had become dislodged from the cervix, the point being imbedded in the posterior vaginal wall almost in midline, at about the level of the external os. After removal with the speculum a ragged penetrating wound, one-half to three-quarters of an inch deep, was seen in the vaginal wall at this point. The other signs were those typical of a large pelvic abscess almost ready to rupture into the vagina. A dressing forceps was plunged through the wound and a large quantity of foul smelling colon pus was evacuated, about two quarts. Drainage was instituted and recovery was rapid and complete. This case was cited as illustrating another of the dangers of the long-continued use of a stem pessary of whatever type. This woman was still wearing a stem for the relief of the same dysmenorrhea. She understood distinctly that it was against his advice; yet she insisted upon it as without it she suffered intensely for two days each month. With the stem she was perfectly comfortable.

Dr. HAROLD BAILEY said he did not think Dr. Ward was justified in putting the stem pessary in that patient again. The woman should have an operation to relieve the anterior flexion.

Dr. WARD replied that he agreed with Dr. Bailey in principle. There were, however, certain cases in the practice of medicine in which one was forced to do what one really did not wish. In this particular case the circumstances were such that it seemed that the only thing to do was to treat her in the temporary absence of her physician as they both desired. She understood clearly that he did not approve of the method, but was entirely willing to assume all the risks.

Dr. S. WIENER supplemented Dr. Ward's case with a similar one which he had seen recently. This woman had also been wearing a perpetual pessary, one of the double-pronged uterine variety worn for the prevention of conception. She had worn it for some time and a large pelvic abscess had formed. The abscess was opened and a considerable amount of foul smelling pus evacuated. The wearing of the pessary had led to the infection and the formation of the abscess. This patient went home apparently well, but returned with a temperature of 102° F. and a mass on her right side above the umbilicus, and just about the middle of the upper right rectus muscle. There was a distinct round tender mass under the skin which proved to be an abscess. The finger could be passed back to the retroperitoneal tissue and undoubtedly this abscess traveled up from the cul-de-sac of Douglas retroperitoneally and pointed above the umbilicus on the right side.

Modern Obstetric Technique, Compared with the Teaching of Twenty Years Ago.—Dr. GEORGE L. BRODHEAD presented this paper, in which he stated that he had had the good fortune to spend two years, 1895 to 1897, as resident obstetrician at the Sloane Hospital, the best service to be had at that time in this country, the instruction being given by Dr. James W. McLane and Dr. E. A. Tucker. At that time there was no part of the daily routine more rigidly insisted upon or supervised than the careful, systematic examination of the pregnant woman. Increasing experience had completely justified these painstaking examinations, which included palpation, auscultation, and pelvimetry. There could be no question as to the value of thorough, antepartum examination. In the writer's early months in the hospital no sterile gowns were used in the conduct of normal labor and rubber gloves were unheard of. At the present time one wore both gown and rubber gloves, and many wore a cap and face mask as in general surgery. In his private work and his work at the Harlem Hospital, Dr. Brodhead said he used the rectal examination in all cases, unless there was a good reason for entering the vagina. He believed that more harm than good resulted from vaginal examinations. Presentation and position could usually be determined by external examination. For the rectal examination no preparation of the patient was necessary, the gloves need not be sterilized, and much time was saved thereby, and with a little experience much information could be obtained. In borderline cases in which cesarean section might be an ultimate operation the rectal examination was almost a necessity. It might be objected that vaginal examination was necessary in order to diagnose prolapse of the cord. In cases in which the membranes ruptured while the head was still unengaged, the vaginal examination should be made, but principally and practically only to ascertain if the cord had prolapsed. He believed with Hirst and others, that ergot, if given, should be administered at the moment of the birth of the child, and for many years he had given ergot in this way with only good results. In other words, the ergot must be given in time to control the hemorrhage by contracting the uterus before the bleeding was likely to occur, and therefore he gave it immediately after the child was born without waiting for the placenta to be expelled. It was their custom at Sloane to invade the uterus for retained membranes. During his last year the retained membranes were left in the uterus, and so satisfactory were the results that he had never explored the uterus for retained membranes since. During the puerperium, it was their custom to order the patient catheterized every eight hours, if she could not void spontaneously. They now knew that patients need not be catheterized if a longer time were allowed, or one c.c. of pituitrin might be given hypodermically, or the woman might be allowed to sit up on the bedpan or chamber. The patient might be allowed to wait eighteen to twenty-four hours with no discomfort and no bad results. Pituitrin was an invaluable addition to the armamentarium of the obstetrician. It was invaluable in postpartum hemorrhage, before cesarean section and as a substitute for forceps in properly selected cases. Personally, however, he believed that with the head at the outlet, the forceps, in skilful hands, was a safer procedure than the use of pituitrin. Pituitrin was also used with sat-

isfactory results in cases of inevitable and incomplete abortion. There was also merit in the suggestion of Furniss that pituitrin be given before curettage for incomplete abortion, with the idea of contracting the uterus and lessening the hemorrhage. The cleaner the surroundings and the greater the care taken by the accoucheur, the less frequently would sepsis be met. The patient who was infected would have a much better chance for life if treated conservatively, with good drainage, good food, and an abundance of fresh air. In speaking of operative procedures, Dr. Brodhead said that episiotomy had not received the attention it deserved. The operation was never performed during his service at Sloane, but a few years later he was impressed with its value and had been using it ever since. It was simple, devoid of danger, and so successful in its results that he believed it was performed far too infrequently. Among the indications for the operation were rigidity of the perineum; edematous soft parts; cases in which large fetal head must pass through small vulvar outlets; the passage of meconium in vertex presentation; a rapid failing fetal heart, necessitating a speedy delivery through a small outlet; where there was a large amount of cicatricial tissue in the perineum, and as a prophylactic measure in breech presentations. The writer confessed to a considerable number of complete lacerations of the perineum in breech cases, but he remembered no instance in which the sphincter was torn after episiotomy was done. With median perinectomy the writer had had only a limited experience, but men who had used the procedure claimed that it was far superior, in that the incision was single and more easily repaired, and there was less probability of tearing up into the vagina. The bilateral operation would naturally give more room in breech presentations and would be preferable. The low forceps operation had steadily increased in favor in recent years, while the high operation had been performed less and less, owing to the prominence that had been given to cesarean section. With the head low in the pelvis, the cervix completely dilated, and failure to advance within a reasonable time, the low forceps operation was safe, and would save the patient in some cases at least hours of unnecessary pain. No doubt the abdominal operation was performed needlessly at times, but there could be no question of the brilliant results obtained where formerly one was doomed to failure when using the high forceps operation. The instrumental rotation of persistent occipitoposterior positions of the vertex, scarcely known twenty years ago but insistently taught by Dr. Tucker, had become a recognized obstetrical procedure of the greatest value. Version still remained an exceedingly valuable and necessary operation. Craniotomy had been performed far less frequently than formerly because of the good results obtained in cesarean section, but it was the writer's belief that craniotomy should be performed much oftener than it was. Many deliveries were completed by high or median forceps operation, or by podalic version, in which craniotomy would have been a much safer operation of election. In placenta previa great advance had been made in the use of the DeRibes bags, followed by forceps or version, or in selected cases by cesarean section. Among the indications given for cesarean section were contracted pelvis, relative disproportion between the size of the head and the pelvis, placenta previa, toxemia of pregnancy, eclampsia, accidental hemorrhage, and contraction ring dystocia. There was one important field for cesarean section and that was in primaparæ at or near term with eclampsia. Vaginal section, unheard of twenty years ago, had been extensively performed and had been found invaluable in properly selected cases. From the third to the seventh month, when it was necessary to interrupt pregnancy for cardiac, renal, hepatic, pulmonary or other pathological conditions, it was frequently the easiest, quickest, and safest mode of delivery. In eclampsia it had not been conclusively proven, in the writer's opinion, to be the best form of treatment, but in many instances it had been used with very satisfactory results. Nitrous oxide to relieve the pain of the first stage of labor had become a great boon and marked a great advance in modern obstetrics.

Dr. HERMANN GRAD expressed the opinion that the paper had presented in a very definite way the great advances made in obstetrical art in recent years, and this was to be ascribed very largely to the fact that more attention had been given to the subject of late than ever before.

Dr. HAROLD BAILEY agreed with Dr. Brodhead that the chances of a complete tear in a median episiotomy were great, and he believed it was not an infrequent occurrence to have these tears in a large hospital service where this procedure was frequently performed. He never did an episiotomy for an oncoming head, but he thought episiotomy was a suitable procedure for an aftercoming head. It was a good plan to have the scissors directly at hand and in position to make the incision if it should be found necessary. Dr. Brodhead spoke of craniotomy as being justifiable in certain conditions even on the living child. He thought the question of doing a craniotomy on a living child was somewhat debatable, and that the cases in which it was justifiable were very few. Dr. Bailey said that it seemed to him that the few cases in which craniotomy might have been said to be justifiable were the ones which presented the opportunity for pubiotomy rather than craniotomy.

Dr. SAMUEL J. SCADRON said that after listening to Dr. Brodhead's paper one came to the conclusion that obstetrics had been taken from the medical man and given to the surgeon. As for the advantages of episiotomy, there was, in his opinion, no greater indication than in the occipitoposterior position where one could not rotate the head. While craniotomy on the living child did not compete with cesarean section and pubiotomy, nevertheless in those cases in which the forceps had been tried and then cesarean section done the mortality was so high that craniotomy in such cases should always be performed, and craniotomy was preferable to pubiotomy.

Dr. BRODHEAD, in closing, said Dr. Bailey had elicited the fact that there were more complete tears with median perinotomy than had been reported. He was undoubtedly correct in this statement, but he thought bilateral episiotomy was very valuable especially for breech and some vertex cases. The occasional case of persistent occipitoposterior presentation in which the head could not be rotated offered an ideal indication for episiotomy.

Placental Polyp.—Dr. Brodhead reported this case and presented the specimen, which he said he brought with the idea of contributing it as a part of the discussion on the cases of uterine polyp that Dr. Falk was to have presented. He stated that the patient was delivered normally about twelve years ago. About four-fifths of the chorion was retained and the amount of hemorrhage was not over eight ounces. The highest temperature in the puerperium was 99.4° F. There was no odor and no membrane in the lochia. About fifteen days post-partum the cervix showed a crescentic laceration, the uterus was anteflexed and fairly involuted but there was no bloody lochia. About eight days later it was found that she had a small tumor, one and one-half by three-quarters inches protruding from the external os with slight bleeding. The mass was found to be attached to the posterior wall by a small pedicle and was easily removed. Microscopically it was shown by Dr. Libman to be a typical mole with numerous chorionic villi. The patient made a good recovery. This was the only case of true placental mole that had come under the speaker's observation.

Dr. HAROLD BAILEY added a case of uterine polyp. He said this case occurred twenty-five days post partum. The woman had a free hemorrhage and became exsanguinated. A polypoid mass with a pedicle was found protruding through the external os. This was removed by pressure on the pedicle. It proved on microscopical examination to be entirely placental. He had had another experience just this month. A case ten days postpartum passed externally a large mass, and the doctor who first saw her thought she had an inversion of the uterus. She was taken to the Memorial Hospital, and at examination under anesthesia that mass was found to be a polyp with a very thick pedicle. This was removed by dissecting the pedicle from the uterine wall by finger pressure. Examination showed this tumor to be a submucous fibroid.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 9, 1918.

DR. HERBERT B. WILCOX IN THE CHAIR.

Pulmonary and Cardiac Cases for Diagnosis.—From the Children's Medical Division of Bellevue Hospital.—Dr. L. E. LAFETRA presented a cardiac case, which he said was somewhat puzzling, the question being whether the boy had an acquired lesion, a congenital lesion of simple type, or one of complex type, or whether he had some disease of the aorta. The boy was 11 years of age, poorly nourished, and weighed 61 pounds. He had had measles and whooping cough at the age of 6 years; his tonsils were removed when he was 7 years of age, and for the past three years he had had something called "rheumatism." His temperature since coming under observation had been normal. The blood count showed 10,500 white cells, 72 per cent. polynuclears, and no abnormalities of the red cells. The urine was negative for albumen and sugar. There was a marked dullness for 2 inches to the right of the sternum, especially noticeable in the upper spaces. There was pulsation in the second and third right interspaces, so strong as to suggest the beat of a ventricle. It was very difficult to make out the maximum apex impulse. It seemed to be to the right of the sternum in the fourth interspace. There was a loud, rough systolic murmur at about the junction of the third left rib cartilage with the sternum, and there was also a faint presystolic and a late diastolic murmur. The murmurs were not heard in the back. There was no enlargement of the liver, no dyspnea, and no evidence of cardiac embarrassment. The *x*-ray showed marked bulging of the heart in the upper spaces of the right side. The aorta showed with a little more prominence than was usual and the heart was characterized by a circular outline. The maximum diameter was at the third rib on the right side and the fourth at the left side. A further point in the examination of this boy was that the Wassermann test was strongly positive. The electrocardiogram showed nothing abnormal aside from hypertrophy of the right side of the heart. The teeth in this case were very interesting. They showed a rather wide spacing between the upper incisors, and the cutting edges were notched. The teeth were badly decayed, so that the defects could not be made out distinctly, but there was a humpy molar on the left side in the upper jaw. As to the diagnosis—in the first place it did not seem that the physical signs were those of acquired heart disease. The shadow and the murmurs did not correspond to those of a child with endocarditis following rheumatism or any infectious disease. In the second place, the shape of the heart with the widening of the shadow suggested a possible transposition of the great vessels, and the location and character of the heart murmur over the sternum suggested a patent ventricular septum. In the third place, there was the possibility that the murmur was due to aortic dilatation from specific disease. Dr. LaFetra's opinion was that the boy had a congenital malformation, probably transposed vessels and patent ventricular septum.

Dr. LOUIS C. SCHROEDER presented this case, a boy, 9 years of age, whose family history had no bearing on his present condition. His birth was normal and he appeared to be normal in infancy except that his mother says he often turned black when he cried. He had had measles, pertussis, and diphtheria, from all of which he made uneventful recoveries. His developmental history was normal. He was brought to the outdoor department of Bellevue Hospital because he had a troublesome cough which was worse at night, and which he had had since the age of six months, and also because he suffered from frequent colds. Physical examination showed nothing of particular interest outside of the heart condition. The boy was offered for diagnosis not because there was any doubt of there being a congenital heart defect, but to determine whether or no the harsh, rough friction sound along the left border was a true friction rub. This murmur, taken by itself, was a very characteristic pericardial involvement, but taken in conjunction with the rest of the evidence, some doubt was thrown upon it. Against the diagnosis of adherent pericardium or pericardial roughening was the fact that there was no history of any rheumatic attacks, there being no characteristic left-sided hypertrophy at all comparable to that usually seen, though of course it might not have existed long enough to have developed sufficiently to be noticeable, nor was there any evidence of acute attacks of dilatation which were not an uncommon sequence of pericarditis. The *x*-ray showed a heart with hypertrophy of both auricles and a displacement of the aortic arch to the left, probably the dilated arch of a patent ductus Botallo. The electrocardiogram showed a left-sided preponderance which, Dr. Kelly had informed the speaker, as far as the congenital condition was concerned, spoke rather in favor of a patent ductus Botallo.

Dr. MAURICE KEMP presented this case, a boy 14 years of age, born in New York, of German-American parents. The father was luetic and died at the age of 39 years of paralysis. The mother was 41 years of age and healthy. She had received antiluetic treatment for thirteen years. She had three other living children besides the patient, and she had had three miscarriages. The patient's birth was normal. He had snuffles for twenty months after birth. His general health was good except for convulsions from the age of six months to eight years. He had had the ordinary diseases of childhood. He was brought to the clinic in April, 1916, for nervousness, and because he had a four plus Wassermann. He was treated with gray powder and seemed to improve. The latter part of July he had an attack of vomiting, followed by unconsciousness. In October, 1916, he sustained a fracture of the right parietal bone. In October, 1917, his mother again brought him to the clinic for his peculiar gait, stammering, peculiar actions (hiding pennies from his bank, etc.) and restlessness in school. When scolded he shook, though not excited. At night there was a back and forth movement of the right leg, whether he was awake or asleep. On returning from Sunday school, on April 21, he had an attack of vomiting and dizziness, and later became stuporous. Physical examination showed the lungs and heart negative, enlarged cervical and axillary glands, a spastic and somewhat ataxic gait, unsteady and occasionally staggering. His feet were rather widespread. His station was normal, with slight unsteadiness, hardly a Rhomberg. The patient showed apraxia, and the finger to nose test showed slight tremor. Speech was variable, hesitating, and at times explosive. The boy did not repeat test phrases. The deep reflexes were all very active. There was patellar clonus. The abdominals were normal; the cremasteric sluggish. There was a Babinsky on the right and left; Oppenheimer and Gordon on the right, and questionable on the left. There might be a slight paresis of the lower extremities. Touch, temperature, vibratory, and muscle tendon senses were normal. The eyes showed deficient convergence; the pupils did not react to light; they were equal and slightly irregular; both discs were pale. The upper temporal margins were somewhat indistinct. There was an absence of retinal pigment, and a slight hyperopic astigmatism. The patient showed two years' retardation and abnormal emotional status. He had a four plus Wassermann. The diagnosis was a probable multiple sclerosis and a beginning juvenile paresis.

Dr. G. PREVITALI presented this case, a boy 11 years of age. His family history was unimportant. His previous history showed that he had pneumonia at the age of 9 and 13 months, scarlet fever at 2 years, pneumonia again at 10 years. Three weeks after this, on October 28, 1917, he came under observation. At this time he complained of not feeling well and of coughing since the last pneumonia. His general condition was poor, heart overactive, pulse rate 108, and temperature normal. There was slight dullness at the right upper lobe and at the left lower lobe posteriorly, with crackling râles. The general condition of the patient improved slightly during the following three months, but the cough persisted. On February 1, 1918, three months later, the dullness of the right lobe was much more marked, and over the same area there were moist râles on inspiration and definite cavernous breathing in expiration. At several examinations since this time the patient had shown

dullness over the lower left lobe, and after expectoration the dullness would increase considerably and the cavernous breathing reappear. At present the expectoration was diminished, the cough was much less, and the physical signs were not so manifest. The patient felt well and had gained 5 pounds in the last five months, having the average weight for his age. Microscopical examination did not show tubercle bacilli in the sputum. The von Pirquet test was negative three times. The Wassermann was negative. Two *x*-ray pictures had failed to confirm their diagnosis of bronchiectatic cavity. They did not consider the case one of tuberculous origin.

Dr. CHARLES HENDEE SMITH presented this case, a child, 11½ years of age, whose family history was negative, save that the father was said to be tuberculous. She had had scarlet fever, diphtheria, pertussis, and pneumonia, and when 6 years of age had a tonsillectomy performed. She was referred from the Gouverneur Hospital with the statement that she had been tuberculous for three years. The mother said that the child had coughed for the past three years, never before. The physical examination showed the child pale but about normal in weight and height. Examination of the heart showed a double mitral murmur. The heart action was poor. The left border of the heart was 5 inches to the left of the midline. The lungs showed dullness and bronchial voice breathing at the left base. The patient was in the hospital or at the Pelham Summer Home from October until January. The lung signs noted on the Pelham chart showed that there were signs of fluid on the left base; by aspiration only 5 c.c. could be obtained. The *x*-ray of the chest showed the heart shadow of chronic valvular disease. On her return to Bellevue the patient gave a negative von Pirquet and a negative Wassermann test. On January 14 she returned to the outpatient department, at which time she had gained in weight and the cardiac condition was much improved, the apex being 4½ inches to the left. At the next visit there were signs of fluid on arriving and, after coughing, signs of cavity. There was an irregular area, 4 by 5 inches, at the left base, over which breathing varied from cavernous to broncho-cavernous, as if there were possibly a consolidated lung with several cavities. The change in signs could be obtained whenever the child came without having coughed for a few hours. The sputum had been examined repeatedly, and no tubercle bacilli found. A second von Pirquet was slightly positive on April 1. The tuberculosis complement fixation test was negative. The *x*-ray showed nothing in the usual antero-posterior views, since the lung lesion was behind the heart, but when the child was turned obliquely, so that the heart shadow was rotated toward the right, an area at the left base showed a diffuse thickening of the lung with two or three small cavities. There were probably more of these behind the heart. The patient had gained 7 pounds in six months. The diagnosis in this case was endocarditis and pulmonary cavity, either bronchiectatic or tuberculous. In favor of a simple fibrosis with bronchiectasis was the good condition of the child, the gain in weight, and the fact that there were no tubercle bacilli in the sputum, together with the fact that the complement fixation test to tuberculosis was negative. In favor of the tuberculosis was the tuberculosis of the father, which implied the exposure of the child to infection, and the plus von Pirquet. It seemed to the speaker that the child was an example of a large group of cases which were not uncommon and which were called tuberculosis, but which were probably simple bronchiectasis.

Dr. JEROME ZUCKERMAN presented this case, the history being read by Dr. Smith. He said this child was 6 years of age, a native of the United States. The father died of tuberculosis six years ago, and the mother of the same disease three years ago. There were two older children, who were well. The patient had had scarlet fever at the age of 3 years, measles and pertussis at the age of 4 years, and varicella at 5 years. About three months ago she had an attack of urticaria. Her tonsils had been removed. Her present illness began about two months ago, with swelling of the hands and a moderate amount of pain. Physical examination made about two months ago showed a fairly well nourished child, pale, and weighing 41 pounds. The examination was negative except for moderate swelling at the metacarpo-phalangeal joints, more especially the left hand. There was a slight general swelling of both feet and enlargement of the cervical axillary and inguinal glands; the epitrochlears were not felt. The knee jerks were exaggerated, and there was a marked Chvostek. The child's condition had remained practically the same up to the present time. The *x*-ray examination of the hands showed an infiltration of the soft tissues, but no evidence of arthritis. The *x*-ray examination of the feet was negative. The von Pirquet was markedly positive. The *x*-ray of the chest showed an adenopathy of the roots of both lungs. The Wassermann was negative and the vaginal smear was negative. For the past few days the child had run a temperature of from 100° to 101° Fahr. This was shown for differentiation between an early Still's disease and tuberculosis, and for the possible correlation between the two conditions. In Still's original description there was a chronic progressive enlargement of the joints associated with general enlargement of glands and enlargement of the spleen. The onset was before the sixth year. There was an absence of osteopathic growth even late in the condition. The affection was symmetrical; there was no tenderness and very little pain. There was an increased temperature appearing during periods and lasting a few days. This child lent herself to this description with the exception of the enlargement of the spleen. But there was also present a distinct family history of tuberculosis, a very positive von Pirquet, and positive *x*-ray findings in the lungs.

Dr. MURRAY H. BASS asked whether this child was fluoroscoped. He said that a few years ago he had reported a series of cases with Dr. Wessler, in which the children showed a patent ductus arteriosus, and the chief interest in the series of cases was that under the fluorscope one could see the sudden systolic dilatation of the small aneurysm in the pulmonary artery; under the fluoroscope this showed very well, but one could not see it on the *x*-ray plate.

Dr. SMITH replied that the fluoroscopic examination had been made and the child showed distinct evidence of tuberculosis.

Erythema Multiforme as a Rheumatic Manifestation in Children.—Dr. MURRAY H. BASS read this paper, in which he said that in spite of much research and theorizing the clinical entity comprised by the term "rheumatism" was still somewhat vaguely defined. In childhood we might define as rheumatism a group of pathological conditions which appeared to be closely associated, and which apparently were due to the same causative factor, since any one of them might be the starting point of an illness in which any or all of the others might make their appearance. This group of pathological conditions included joint pains and joint swellings, muscular involvements, such as torticollos; cardiac affections, either endocardial, myocardial, or pericardial, chorea, tonsillar infections, and certain skin manifestations, mainly erythema nodosum and erythema multiforme. To this disease complex the name rheumatism was correctly applied. Though there was no strictly pathognomonic clinical sign or symptom of rheumatism, we did possess sufficient data concerning its pathological anatomy. The lesions found in the heart were characteristic, consisting of small, firm, grayish-pink wart-like nodules situated on opposing surfaces of the valves along the line of closure. On section bacteria had rarely been demonstrable, and then in very small numbers; the only organisms found in section or on culture, according to Libman, were streptococci. Very characteristic changes were also to be found on the myocardium in the form of microsconic foci, forming submiliary nodules. These bodies, described by Aschoff and known as Aschoff bodies, consisted of aggregations of large cells scattered through the myocardium, mainly in the subendothelial portion, in the course of the medium-sized and smaller blood vessels. Dr. Bass reviewed the conclusions of Aschoff and of Thalheimer and Rothschild, which showed that they considered these bodies as characteristic of rheumatic infection. Thalheimer and Rothschild suggested that the cases of arthritis characterized by the presence of the Aschoff bodies in the myocardium be placed in

one group and called for the time being "rheumatism" and the cases with articular manifestations, yielding positive bacterial findings and no Aschoff bodies should be classified according to the infectious organism concerned, and not as rheumatism. We had therefore in the Aschoff bodies a pathognomonic sign of rheumatic infection, and one which might be safely used to identify the disease. Dr. Bass reported in detail a case in which the diagnosis of an unusually virulent type of infection was definitely proven to be rheumatic by the post mortem finding of the Aschoff bodies. Briefly the case was that of a child, 3 years of age, who had a severe tonsillitis, followed one week later by an eruption of erythema multiforme, and one week later by endocarditis, with death from heart failure after four days. The microscopical examination of the heart showed great numbers of typical Aschoff bodies present throughout the section situated in the interstitial tissue and also around the blood vessels and in the adventitia. The mitral valve was thicker than normal, and showed a very irregular arrangement of its connective tissue cells in places, these being arranged in whorls. The connective tissue cells were in places widely separated from each other, evidently by serum, giving the appearance of edema. In these places the cells were branching and resembled embryonic connective tissue. There was a diffuse infiltration with mononuclear leucocytes. There were no definite Aschoff bodies present, but in places the endothelium of the surface of the valve was thickened, being made up of several layers of cells, and from these situations columns of endothelial cells were apparently growing down into the valve. These cells somewhat resembled Aschoff cells. On the edge of the valve there was an irregular hyaline thrombus apparently being organized, as fibroblasts extended into it for quite a distance. Some of the fibroblasts were very large, and also resembled Aschoff cells, although they were not identical with them. With Unna Pappenheim's stain the Aschoff bodies stained a bright red and were sharply differentiated from all the other cells. At autopsy the lungs showed marked congestion and there was a bilateral hydrothorax with clear straw-colored fluid. The liver and spleen showed great congestion so virulent that bacterial endocarditis was suspected. The autopsy findings, however, disposed of this diagnosis nad absolutely proved the rheumatic origin of the disease. Erythema as a rheumatic manifestation was not particularly common in childhood, being a more frequent manifestation of the disease in the adult. Dermatologists did not seem to agree as to the exact nature of these eruptions, some regarding them as superimposed infections while others regarded them as the results of toxin action of the disease itself on the skin. The eruption might take one of a number of forms—the lesions might be papules, vesicles, wheals, nodes, or a combination of these, and they might be hemorrhagic. The author reported one type of case which closely resembled urticaria. Others seemed to combine some of the characteristics of erythema multiforme with those of erythema nodosum. The writer had recently observed such a case in a child, four and one-half years of age, who suffered from repeated attacks of mild joint pains accompanied by exquisite tender swellings of the skin. The attack observed started in with fever 101° F. and swelling over the anterior surface of the tibia, which was thought at first to be a periosteitis, but a radiogram showed the bone to be absolutely normal. The Wassermann reaction was negative. When seen two days later the swelling involved the skin over the entire tibia. It was hot and exquisitely tender. A second similar swelling was beginning to appear over the right elbow. A diagnosis of rheumatic erythema was made and large doses of salicylate prescribed. Two days later the eruption had practically disappeared. Such an eruption could not be classified as an erythema nodosum on account of its transitory nature. The author reported a third case which showed the relationship existing between the erythema and the other symptoms. In this child after a slight joint pain, the skin lesions appeared. Three weeks later the child developed a chorea, and one week later a mitral endocarditis. A year later there was an identical eruption which seemed to be improved by the administration of salicylates. In concluding Dr. Bass said that their autopsy case was the first in which an illness, one of the symptoms of which was erythema multiforme, had been pathologically proven to be rheumatism by finding of Aschoff bodies in the heart muscle. These case histories were of importance since they showed that children exhibiting this type of eruption should be considered rheumatic and sick enough to be kept in bed in order, if possible, to avoid the other and more serious complications of rheumatism.

Dr. Oscar M. Schloss said that Osler gave his attention to the erythemas and classified them into erythema multiforme, angioneurotic edema, and certain purpuras, and he drew attention to the fact that associated with these conditions were endocarditis, pericarditis, and rheumatism. In 1910, the speaker reported four cases as belonging to this group. Two of these cases had a definite rheumatic involvement connected with the erythema multiforme and urticaria and two represented erythema nodosum and erythema iris. The other patients had a distinct rheumatic history. There was no question that these findings of Dr. Bass were of the greatest importance. The work of Aschoff Frankel, Thalheimer, and Rothschild, showed that these Aschoff bodies were characteristic of rheumatism, and short of finding the actual organism which caused rheumatism, this was the most particular evidence one could have as to the relation of the erythema group of Osler to rheumatic fever.

The Treatment of Acute Intestinal Intoxication.—Dr. Oscar M. Schloss read this paper. (See Medical Record, May 25, 1918, page 921.)

Recent Studies in the Physiology of Tendons and Their Application to the Operative Treatment of Poliomyelitis.—Dr. Leo Mayer presented this contribution. He said that the interest in the anatomy and physiology of tendons was first aroused by the problem of preventing post-operative adhesions. Working in conjunction with Dr. Henze of New Haven, the speaker, in 1912, discovered that the essential principle in the prevention of adhesions was the maintenance of the normal relationship between the tendon and its sheath. To render this principle practical to operations for poliomyelitis paralysis, an extensive research into the anatomy and physiology of tendons was necessary. The results of this research showed that the tendons were equipped with a delicate, gliding mechanism, the essential of which was a peculiar elastic tissue, known as the paratenon, which enveloped the tendon and permitted it to move to and fro beneath the rigid fascia. At the upper pole of the tendon sheath, this tissue was prolonged downward, as a kind of tongue which acted as a valve maintaining the closed character of the sheath, and at the same time permitting the gliding motion of the tendon. This gliding mechanism of the tendon could be retained in tendon transplantation by appropriate technique, the details of which were given in a work entitled the "Orthopedic Treatment of Gunshot Injuries," published by the Saunders Company. The speaker then demonstrated by lantern slides the results obtained by tendon transplantation performed according to the physiological method.

Death Attributed to Obesity.—Maranon describes the case of a woman of 29 years of age who weighed over 345 lbs. Her height was 5 feet 2 in. The type corresponded to Ebstein's third degree. She was vain over the distinction of being so fat. She had contracted syphilis and had never been thoroughly treated; she herself attributed the obesity to that disease. Menstruation had completely ceased. Physical examination showed normal circulatory conditions and a few days before her death she was feeling in excellent health. The decease was sudden and an autopsy was therefore obtainable. To the naked eye there were no pathological alterations of any kind. The glands of internal secretion were all examined with the microscope. The author concluded that they had been attacked by a sclerotic process of syphilitic origin. The hypophysis appeared to be affected to a greater degree than the other organs. The exact mechanism of death was none the less obscure. In the discussion which followed Espina reported a case in a man of pluriglandular obesity, similar to the preceding. This patient also died suddenly but he was known to have had sugar in the urine.—*El Siglo Médico.*

A THERAPEUTIC SUGGESTION CONCERNING ENDOCRINES.

BY SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE human body is managed by the endocrine glands of the body. You have an automobile, and it is run by gasoline of one kind. In spite of the fact that it has a competent mechanism, if you are short of gasoline, or have a poor quality of gasoline, that invalidates the value of the automobile. But in the human body you have many kinds of gasoline given off by many glands, each gland producing many secretory elements. The particular division of these secretions we do not yet understand, but each gland and its special components has a definite specific action; and every individual from the time he is born until the time he dies is under the influence of these many different kinds of elements—some of them having to do with the development of the bones and teeth, some with the development of the body and nervous system, some with the development of the mind, etc., and, later on—with the introduction of sex features—with reproduction. Still later on, these elements have to do with the preservation of these structures and functions which constitute the body and mind, and if the gasoline elements which are given off by these glands become under- or over-active there is a disturbance of the specific functions which these component parts are supposed to perform; and since these glands are dependent on each other, the upset of one disturbs the rhythmical action of the others; so that accordingly a woman during her development and maturity keeps in action as her glands keep in normal action; and as she approaches the climacterium and, later on, the years of senility, her glands change and her activities change, so that if she lives long enough she is pretty nearly back to where her body functions started in the early years.

In recent years our knowledge as to the physiology of the ductless glands has been put to the test by endocrine therapy, and there is no longer any doubt that the future of medicine lies along these lines. In my own practice, endocrine therapy has displayed and replaced the old time drugs, so that I might safely say that practically 90 per cent. of all prescriptions for internal use consist almost entirely, if not wholly, of endocrine extracts. The varying forms of amenorrhea, most of the menorrhagias and metrorrhagias, threatened miscarriage, habitual miscarriage, sterility, the disorders and disturbances of the climacterium, and many other states met with in gynecological practice may be corrected in many instances specifically by a certain extract; in many other cases, by a combination of extracts.

We know what many of the gland extracts will do, but we have not yet solved the question as to how many various elements enter into the secretions produced by any of these glands. We know the difference between the adrenal medulla and the cortex, between the anterior and posterior lobes of the pituitary, between the interstitial secretion of the ovary and that of the follicle apparatus, and in all probability will some day find the following explanation: Many of these internal glands secrete more than one element, each of these elements acting directly on certain structures, or nerves, or nerve ends, and having definite stimulating, trophic, or inhibiting functions. On the other hand, such of the gland elements as we know have a varying selective action according as they act on the bones, or the muscles, or the mucous membranes, or the musculature of the hollow viscera, or on certain nerves, or on the branches of certain nerves, or on the nerve ends. With either of these ideas in mind it is easy to picture all of the functions of the body carried out by the proper relation between stimulation and inhibition.

The selective activity of the endocrine products is easy to understand. Pathology has taught us much that leads to a proper understanding of physiology. In anterior poliomyelitis there is a selective action by the toxins on certain cells in the anterior horns; in locomotor ataxia there is a selective action of the toxin on the posterior column of the spinal cord; in shingles, some toxin acts on definite nerve roots. Hence it is no stretch of the imagination to conclude that nature has conferred on the ductless glands of the human body control over practically all its functions by giving to certain elements definite, specific activities.

Whatever sequelæ and complications the internist many find in influenza at the present time, the gynecologist and obstetrician has his attention fixed very decidedly on the endometrium, whether the patient is pregnant or not. I have had several patients, not pregnant, whose menstruation came on early and excessively shortly after an attack of influenza. Several pregnant patients have spotted and stained after slight attacks of influenza. One patient miscarried in the fifth month after a pneumonia; and another, after a slight attack with no pneumonic process.

The uterus is a lymphoid tissue, and I have come

to the conclusion that the uterine mucosa by its sensitiveness to the influenza toxin proves that the disease affects markedly the thymico-lymphatic system, and that when this barrier is passed the toxins act most disastrously on the pituitary and adrenal structures; so that the specialist in diseases of women may readily come to the conclusion that the influenza toxin—from his standpoint, at least—has, if not a selective action on the endometrium at least a predilection in that direction.

Trophic control over development and growth, and the maintenance of the normal state in the various structures of the body is vested in the ductless glands, and immunity or lack of immunity to various diseases is more than probably one of the most direct evidences of their important functions. Normal relation of these gland elements, whether their action is exerted directly on the tissues in question or upon the structures through the medium of the nerves and nerve ends, preserves a proper state of growth; and the lack of trophic care or an overstimulation of tissue cells and epithelial cells must lead to abnormal growth. In this view of the question, I believe will eventually be found the cause of benign and malignant growths of the body.

Dermoid cysts represent the growth of embryonic elements displaced in clefts during the development of the embryo, or of such elements—located, for instance, in the ovary—which at first dormant, are not inhibited and are at some later period stimulated to growth. That many of these cells have lain dormant for years and have then taken on a growth, proves the question to be either lack of inhibitory control or overstimulation.

Chorioepithelioma is, after all, the very best evidence of lack of inhibition or over-stimulation in the mother afflicted with this condition. Certain cells of the ovum's outer layer have been retained in a uterus after a miscarriage or a full-term pregnancy, and after a few months, or even after two or three years, these develop into a malignant growth characterized by metastatic deposits carried through the blood channel. It is perfectly evident that these cells have grown either because a protective ferment or element is lacking in the individual in whose uterus these cells have developed the above mentioned growths or because an overstimulation exists which forces these cells and fosters their growth.

The uterus of every woman is the potential carrier of myoma or fibroma. If she bears children and the uterus is engaged in carrying out the functions for which it is prepared by the action of the ovary, thyroid, pituitary, and other glands, there is certainly less likelihood of fibroma or myoma developing through hyperpituitarism than if she have no children.

For instance, we have the pituitary gland, especially the posterior lobe, which is often hypoactive. We know that a woman grows stout, menstruates less and less, and has an atrophy of the uterus and ovaries, often permanent, when the posterior lobe underacts markedly for a long period of time, this condition being called dystrophia adiposogenitalis. Therefore, on the basis of both theory and practice, we know what hyperactivity of this lobe should produce. It overstimulates both ovary and uterus, and in all probability is the cause of fibromata and myomata of the uterus and of the condition known as fibrosis uteri, in which condition, at operation, the ovaries are found large and hyperplastic and certainly are overactive.

There are so many manifestations of hyperpituitarism that are probable but not yet definitely settled, that it may seem almost theoretical to mention some of these states. For instance, many cases of dysmenorrhea are cases of hyperactivity of the pituitary lobe at the menstrual crisis. Again, I recently operated on a patient suffering from what was diagnosed as prolapse of the uterus, the cervix appearing at the vulva. She had had no children, in fact, was unmarried. I diagnosed it as a case of elongatio colli, with retroflexed uterus. The uterus was more than twice the normal length. I amputated the cervix at the level of the internal os, and the amputated cervix was certainly over three inches long. In talking on this case during this step of the operation, I stated that this condition, as well as fibroids and fibrosis of the uterus, was an evidence of some hyperactivity of the posterior lobe. When I opened this patient's abdomen in order to correct the retroflexion, I found a large uterus with a fibroid the size of a walnut on the fundus. This, of course, might have been, unless my theory is right, simply a coincidence, but I believe the above expressed view to be the correct one.

I wonder if the following case is to be viewed as merely a coincidence: Patient, married six years, 2-para, menstruates every twenty-eight days, duration four to seven days, large in amount. Her premenstrual phenomena are sleeplessness and frequency of bowel movements, which have become more marked in the last year. Her blood pressure was 140, and my diagnosis was hyperpituitarism, combined possibly with hyperthyroidism. In asking her whether she had nursed her second baby, born two years ago, she replied, no, because the baby had suffered from pyloric spasm and had been operated upon for the same. If the whole question of heredity is, as I believe, mainly a matter of inheritance of endocrine relationship, then this hyperpituitarism in the mother and pyloric spasm is more than simple coincidence.

We know that the history of a patient's premenstrual phenomena constitutes one of the most important diagnostic aids in all gynecology, for at this period, which is a crisis, interglandular weaknesses are brought into the foreground. Many patients suffer from marked headaches at and during this period; others suffer from nausea and vomiting, and these undoubtedly represent overactivity on the part of related glands, among which the pituitary is certainly most active at menstruation.

When a patient is pregnant and the menstrual activities of the ovary, thyroid, and pituitary are nullified and held in check by the placental secretion, we have a constant struggle between these two—secretions of the mother and the secretion of the ovum—during the entire 280 odd days of pregnancy. If the placental secretion cannot hold the maternal secretions in check, the latter assert themselves and the patient has a miscarriage. This is the explanation of repeated, habitual miscarriages, and hyperpituitarism of the posterior lobe plays an important part in this condition.

Many pregnant patients are not nauseated at any time while they are carrying an ovum *in utero;* others are nauseated in varying degrees. I have frequently noted that many patients who are not nauseated are quite drowsy and sleepy. I am accustomed to tell such sleepy patients that this is a favorable sign, as nausea is not a probable annoyance from which they will suffer. This nausea and vomiting represents a reaction on the part of the system to the introduction of the placental secretion. If a stable adjustment results quickly, the nausea disappears quickly. In this readjustment, undoubtedly (in the cases which vomit and vomit decidedly), we are concerned either with a toxic influence produced by the placental extract or with an exaggerated reaction on the part of the posterior lobe, with hypersensitiveness of the gastrointestinal tract. How great a part transient forms of pyloric spasm play in this persistent nausea and vomiting remains to be decided. Those patients who are sleepy and drowsy (and these are not nauseated nor do they vomit) have the opposite condition—an underactivity of the posterior lobe.

I have always considered fibrosis to be due to hyperactivity of the ovaries. Now that we know the special relation of the pituitary to the ovary and the uterus, we realize that at the menopause period, when gland activity as it relates to the sex-structure should diminish, these glands may, on the contrary, remain active or hyperactive. This will give at the menopause period ovaries which do not regress, a uterus which is overstimulated, with the result that the patient has a menorrhagia or metrorrhagia, a large uterus, and large ovaries at a time when atrophy should be in view. Therefore, the study of any change occurring in a patient at the climacteric period (many of these changes begin years before the menopause comes on) must concern itself with the question of regression. If ovary, thyroid, and pituitary gland diminish in activity harmoniously and in the same ratio, the patient develops amenorrhea, atrophy of the genitalia, with no symptoms of hyperpituitarism, or hyperthyroidism, or hyperovarianism. If the regression is too rapid for the body needs, we have rushes, due to sudden loss of ovarian stimulus; or hypothyroidism, if the same condition takes place in the thyroid; or hypopituitarism, if the hypophysis shows the same rapid decline.

When we consider that one or other of these three glands, leaving the adrenals and other secretory structures out of consideration—may regress much more quickly or more slowly than the other two; and that various combinations of these processes may take place, we see that we may have in any patient various combinations of hyperactivity or hypoactivity which need not be permanent but which may change and fluctuate at this period, so characterized by instability that the laity have well named it "change of life." It is no rare thing to see a patient during or after the menopause suffering from alternating hyperthyroidism and hypothyroidism, and the same is true concerning the pituitary and the ovary.

In the condition, to which we have already referred, known as dystrophia adiposogenitalis, the patients are very sugar-tolerant and may be given large amounts of glucose without sugar appearing in the urine. By theory and by observation, it must of necessity be concluded that overactivity of this lobe will make the patients very slightly tolerant of sugar, and this is undoubtedly one of the important causes of glycosuria. We know the relation of the pancreas to glycosuria, but we have not, in practice, at least, given sufficient attention to the relation which the ovaries, and more especially the thyroid and the pituitary, bear either to the pancreas directly or to the sugar-forming or sugar-retaining qualities of the body. Therefore many patients with fibromata and myomata have glycosuria, many of them have tachycardia, which means either a coincident involvement of the thyroid or tachycardia from hyperpituitarism indirectly.

Whether this overactivity of the pituitary plus the overstimulation of the thyroid has anything to do with gallstones, I do not know. We do, however, observe frequent association between fibromata of the uterus, the post partum period, and stones in the gall-bladder.

In gland therapy we must realizez that it is easy to administer the extracts when any gland fails in action. We simply supply what is needed. The more difficult and eventually glorious part is to overcome the hyperaction of any gland; and this must be done by selecting those other extracts which counteract or antagonize this activity.

In searching for endocrine elements that are antagonistic to the posterior pituitary lobe, we may take these three points into consideration. Mammary gland formation and mammary gland extract certainly have the effect of diminishing menstruation, contracting the uterus, shrinking fibroids, and limiting the activity of the ovaries. We must presume that it may have the same effect upon the posterior pituitary lobe.

The thymus has the effect of controlling the activity of the gonads until the developmental age comes on, after which the thymus is supposed to regress and allow the sex arrangements to develop. We know, then, that thymus extract, if given therapeutically, will in certain cases diminish menorrhagia and metrorrhagia through action on the ovaries. It may have an effect on the posterior pituitary lobe.

When a woman is pregnant, the placental secretion inhibits the menstrual activity of the ovary, plus the thyroid and the posterior pituitary lobe. Therefore we may have in placental extract a secretion that has some controlling influence over the posterior pituitary lobe. If this be so, it should help us in the treatment of dysmenorrhea due to posterior lobe hyperactivity, and should help us in those cases of glycosuria due to the hyperactivity of the posterior hypophysis gland. I have helped, not cured, many patients suffering from dysmenorrhea, by giving placental gland extract by mouth and by hypodermic. I have had remarkable results in several cases of glycosuria at the climacterium, seeing the urine clear up and the sugar disappear by the administration of placental gland extract, with very little restriction of the diet.

We may then conclude that certain forms of glycosuria, if they be dependent on pituitary lobe hyperactivity, should react and improve if placental extract be given.

If the mammary gland and the thymus, in addition to acting on the uterus and the ovary, also inhibit the posterior lobe, they should be tried, if not in other forms of glycosuria, at least in the form of which I have just spoken. How many cases of hypertension or increased or raised blood pressure, especially those noted in women at the menopause or subsequently, are due to hyperactivity of the posterior pituitary lobe remains to be decided. At this menopause or climacteric period, when the activity of the ovaries is supposed to diminish, when there should be and often is a regression in activity on the part of the thyroid, we expect that the posterior lobe will regress too, since the patient's sex activity is no longer of importance. This regression, however, often fails to take place.

My purpose in setting down these views is to direct attention to the possible value of thymus extract, mammary extract, and especially placental extract in those conditions due to hyperpituitarism, among which are certain cases of glycosuria.

The influence and activity of the endocrine glands are evidenced by the stimuli and the changes produced on the body, the nervous system, and the psyche. In some instances abnormalities of gland activity are characterized by physical stigmata; in others, by changes in the activity of organs whose function is continually under the influence of the nervous system; in still other individuals, abnormalities of gland activity are evidenced by changes in the psyche; and in some, combinations of various forms are in evidence. If we can fathom and understand what the ductless glands have done to an individual up to the stage of puberty, we may appreciate why the individual develops as he does; if we can reason out what these ductless glands have done to that individual from puberty up, we may understand why that individual is what he is and why so many changes have occurred in him; if we can eventually fathom what hereditary or accidental and intercurrent factors are responsible for his gland changes and for the consequent systemic, mental, and psychic factors, then medicine will have achieved a glorious work.

134 West Eighty-seventh Street.

TUBERCULOUS BACTERIEMIA AND MASSIVE EXOGENOUS TUBERCULOUS INFECTION IN MAN.

By GEORGE E. BUSHNELL,

WASHINGTON, D. C.

COLONEL M. C., U. S. ARMY, RETIRED.

Much has been written upon the subject of tuberculous bacteriemia in man and very widely varying experimental results have been reported. Some investigators have found tubercle bacilli present in a very large percentage of cases, others find them but rarely under similar conditions. The antiformin method of concentration of the bacilli of Uhlenhuth and its various modifications has been attacked and the claim has been made that the stained objects seen were not tubercle bacilli but artefacts. It has also been claimed that the acid fast bacilli demonstrated were not tubercle bacilli but saprophytes which grow in distilled water or in the water taps, or circulate normally in the blood of rabbits, also that the lesions found in animal experiment are not always tubercles, etc. Liebermeister[1] has made a series of investigations with the use of Schnitter's modification of the antiformin method in which he employed extraordinary precautions to avoid these sources of error and reached the following results: In fifteen cases of open pulmonary tuberculosis he found acid fast bacilli in every case, in thirteen cases of closed pulmonary tuberculosis in eleven cases. Bacmeister is not willing to admit that the bacilli thus found are pathogenic. While it must be conceded that some of the investigators who find tubercle bacilli present almost universally in the blood have not always exercised due caution in guarding against error; on the other hand the methods of the critics themselves are also sometimes open to criticism, as for example the choice of the rabbit for inoculation with human tubercle bacilli, it being well known that the distinction between human and bovine tubercle bacilli is usually made on the assumption that human tubercle bacilli are not pathogenic for rabbits. Fortunately we can spare ourselves the task of a full review of this most perplexed subject, for if necessary we can afford to give up the results obtained by the antiformin method and rely solely upon those of the inoculation of animals. These give unquestionably positive results. Bacmeister,[2] the severest critic, concedes that the animal experiments of Liebermeister withstand criticism and states that to Liebermeister is due the credit of having proved that virulent tubercle bacilli circulate in the blood much more frequently than has hitherto been supposed. We will therefore confine ourselves to his work. In one hundred cases of tuberculosis Liebermeister obtained forty positive results. He had six positive cases in persons without clinically demonstrable tuberculosis, the total number of cases examined not being stated. In his judgment a positive result proves the presence of tubercle bacilli in the blood, but a negative result does not necessarily prove their absence. In other words, animal inoculation is a reliable test, but it is not sufficiently sensitive. Liebermeister used three to six c.c. of blood in his injections and found that, even in cases of severest tuberculosis, of three guinea pigs injected with the same blood only one or two fell sick, which is to be explained, he thinks, by the rarity of the organisms in the blood, their death, and the presence of immunizing substances in the blood. Now if we suppose that 6 c.c. are used as injection and that six tubercle bacilli constitute the minimum infecting dose, as has been stated by another authority, then assuming the volume of the blood to be 5000 c.c., since the blood taken from an arm vein remote from probable tuberculous lesions should fairly represent the general condition of the blood as respects the presence of tubercle bacilli, we should have, as the minimum concentration of tubercle bacilli which would infect, one tubercle bacillus per cubic centimeter, or 5000 tubercle bacilli circulating at one time in the blood, a very respectable bacteremia indeed. Calmette,[3] using the method of direct transfusion of blood from tuberculous to healthy guinea pigs, states that the results proved conclusively that even in mild tuberculous infection the blood almost always contains tubercle bacilli.

It would appear then that the reason why positive results are not obtained in a larger percentage of cases of tuberculosis by the inoculation of their blood into animals is rather that an insufficient amount of blood is employed under the ordinary conditions of experiment than that tubercle bacilli are absent. But it is not necessary to claim so much. If tubercle bacilli circulate in the blood of the consumptive even occasionally during the localization of the disease to the lungs—often a period of many years—the fact that a generalized miliary tuberculosis does not result can only be explained by an immunity to the presence of the tubercle bacillus at parts remote from existing lesions which is fairly comparable with the immunity observed in animal experiment.[4] The tuberculous guinea pig suffers no harm from injected tubercle bacilli. The consumptive patient suffers no harm from the tubercle bacilli which escape from his lesions. He suffers no harm, that is, during the period of localization. Just before death a generalized miliary tuberculosis often develops in the chronic case which has resisted hematogenous extensions of the disease for many years. The dissemination of tubercle bacilli at the close of life may be somewhat greater than in the previous course of the disease, but the difference is one of degree only. If the presence of the tubercle bacillus in the blood meant miliary tuberculosis the patient would have died long before. The reason that tubercle bacilli circulated harmlessly during a long time was that they were prevented from colonizing by the processes of immunity. When the vital powers fail rapidly and cachexia becomes marked the cells no longer furnish the protective substances, and general infection takes place. This view is corroborated by the observations of Fischer,[5] who saw reactivation of tuberculosis from old fibrous glands in the cachexia of cancer, and other wasting diseases, active tuberculosis elsewhere in the body being absent.

We are warranted in saying that under ordinary conditions the consumptive is immune to tubercle bacilli which circulate in his blood. It remains to inquire what the resistance of the human body already infected with tuberculosis is to massive injections from without. There is naturally less evidence than has been obtained by experimentation upon animals, but sufficient when properly analyzed to prove that here also man does not differ in his resistance from the tuberculous animal of experiment.

Kleine[6] gives the following facts as to inoculation with bovine tubercle bacilli: In Königsberg half a dozen patients with cancer were inoculated subcutaneously with bovine tubercle bacilli which had been shown to be virulent for rabbits. Abscesses foci appeared locally, containing at first tubercle bacilli in abundance. These foci healed gradually. The patients lived from some months to a year. At their autopsy v. Baumgarten found small scars at the point of inoculation which were free from tubercle and tubercle bacilli. There was no trace of tuberculosis in the neighboring glands nor in the internal organs. Carl Spengler injected himself with 0.5 mg. of a suspension of living bovine tubercle bacilli subcutaneously. An abscess formed and broke down in a month. A few tubercle bacilli were present. The ulceration lasted eight months, then closed, leaving a pigmented scar. The regional glands were never even transitorily painful or swollen. The infection remained completely localized and gave the impression of being entirely benign. Klemperer, after twice rubbing a suspension of bovine tubercle bacilli into shallow cuts without producing the slightest local reaction, injected 0.25 c.c. of a suspension of virulent bovine tubercle bacilli subcutaneously into his left arm. At the point of injection there was a lively inflammation without fever, which declined in a few days. After two weeks there remained a painless roundish tumor of about walnut size, which finally, as a small chronic inflammatory infiltration of the subcutaneous tissues, was extirpated after ten months. Nothing characteristic of tuberculosis was found. Of the regional glands only the cubital of the left elbow was swollen for a short time. Klemperer injected into a colleague first 0.25 c.c. then 0.5 c.c. of a suspension of bovine tubercle bacilli into the left arm subcutaneously. As notwithstanding local symptoms (not described) the general condition was relatively good and the weight even increased, injections were continued for therapeutic reasons. From March 26 to the middle of May Klemperer made twelve injections of 0.25 c.c. at one-half week intervals into the sides of the abdomen. These were at first borne excellently. There was only slight, sometimes no fever, no swelling, no pain. Only on the right side where several injections were placed close together was there marked infiltration and an abscess finally formed which was some time in healing. This was ascribed by Klemperer to the nearness of the injections to one another. Klemperer made in all fifty-four inoculations on six patients. These were borne well. The local disturbances were slight. Four times there were abscesses which healed more or less rapidly. There were no general disturbances in any case. The patients even reported subjective improvement and gain in weight.

Occasionally the accidents of the laboratory give an opportunity for massive infections. A workman twenty-eight years of age, in consequence of the breaking of a 10-liter bottle, spilled the fluid containing enormous quantities of living tubercle bacilli over his clothing. He was healthy at the time of this accident, but two years later pains appeared in the left chest and pulmonary tuberculosis became manifest. A sister of the workman having fallen sick with pulmonary tuberculosis nine years before, a family tendency to the disease was assumed. A connection between the accident and the later disease of the lungs could not be established. His claim for damages was rejected by the courts.[7]

A similar instance is known in which a workman dropped and broke a bottle containing dry tubercle bacilli, but received no harm therefrom.

A quack in Brooklyn advertised a cure for consumption. He procured a tuberculous cow and induced a woman to submit to inoculation into the neck of virus obtained directly from the diseased animal, an examination having previously been made by three physicians who certified that she was entirely free of tuberculosis. In a short time—too short a time—the claim was made that she had become tuberculous, and this was also certified to by physicians. The advertised treatment was then

administered and in a remarkably short time she was declared to have quite recovered from the disease. The woman not long afterward committed suicide, and the autopsy discovered no evidences whatever of tuberculosis.[8]

Butchers frequently receive infection with bovine tuberculosis in cuts upon their hands, and similarly the "anatomical wart" of the pathologist is due to infection at human autopsies. In both cases the infection remains local and harmless, although on account of its location it is exposed to frequent irritation and may be slow in healing.

The greater part of the foregoing evidence relates to infection with bovine tubercle bacilli. They were used in the experimental inoculations in the belief that they are relatively innocuous to man. This belief has its origin in the observation that the milk of tuberculous cows appears to be harmless for the human adult. But recent investigations have shown that bovine tuberculosis is not uncommon in children, the difference between them and adults being manifestly due to the fact that the child is not immunized against tuberculosis, whether of bovine or human origin, but the adult is. The bovine and human strains of the tubercle bacillus are closely allied, in fact there is some evidence which goes to show that the bovine bacillus undergoes changes during a long stay in the body of man which assimilates its characteristics to those of the human bacillus, and it is hard to explain the fact that bovine tubercle bacilli are common in children, but rare in adults, on any other hypothesis than the assumption that bovine bacilli in time practically become human bacilli.

If this is the case the evidence above cited abundantly proves that the man who has received a primary infection with tubercle bacilli becomes thereby immunized not only to the bacilli from his own lesions, but also to the massive introduction of bacilli from without. That this should prove to be true is to be expected from the manifest analogies which exist between the tuberculosis of man and that of animals. The facts derived from the experimental inoculation of animals may safely be employed to explain the phenomena of human tuberculosis.

TUMORS OF THE BLOOD.

By E. H. P. Ward, M.D.,

White Plains, N. Y.

In an article on tumors published in the *New York State Journal of Medicine* for March, 1907, I advanced the view that a tumor results from the arrested development of one or more cells of the tissue in which the tumor originates and of which it is characteristic; this arrest of development resulting in an atavistic reversion whereby the cell or cells affected, and those resulting from their multiplication, fail to perform their normal functions in the tissue and start off on a more individualistic course marked by more rapid multiplication of a more or less irregular type, tending toward degeneration, and reverting to some of the qualities of the ancestral unicellular organism, such as being able to live a more or less detached life apart from their proper tissue. As a secondary feature, the supporting and nourishing tissues are led astray to a greater or less extent and try to keep pace with the growth of the aberrant cells. And the pathological results of tumors on the organism are due to: (1) the failure of the tumor cells to perform their proper functions; (2) the mechanical effects of the original tumor mass and its metastases; and (3) the production of toxins and other effects due to the altered metabolism and degeneration of the tumor cells and their supporting tissues.

We are, of course, familiar with the occurrence of arrested development in entire tissues and organs, and in some cases very striking atavistic reversions result—as, for example, hare-lip, cleft-palate, persistence of branchial clefts, *spina bifida*, patent *foramen ovale*, and others as numerous as the tissues and organs of the body. It has been a long and complicated process of development from the amoeba to man, and no doubt many were the failures by the wayside. Existing forms of metazoa represent the survivors still plodding along on life's journey, we know not to what goal. But each individual organism in its development has, more or less completely, to recapitulate the life-history of its kind, from the single cell to the mature organism, adding what new features it may; and it is only to be expected that many failures in development will result, not only in organs and tissues but in individual cells as well. In fact, if we did not find the answer at hand in the form of tumors, we might well question why the development of individual cells in tissues did not sometimes become arrested, and speculate as to what might happen if it did.

As to the *cause* of arrested development, whether in single cells, organs, individuals, or races, it may be some injurious influence of chemical, mechanical, or other nature that we can recognize, or it may just happen. We do not know what life is or why organisms and their cells develop at all; how then shall we be able always to say why they fail to develop? Does an ignorant savage, seeing for the first time an automobile, broken down by the roadside, know what caused it to stop, when he has not the remotest conception of what ever made it go? No more can we comprehend the underlying strata of life, which crop up in unexpected places to add to the roughness of our journey.

But after writing the article referred to above, and in thinking further on the subject of tumors, it occurred to me that if a tumor is due to the arrested development of a cell, then each type of cell in the organism ought to have its characteristic tumor. And, of course, there are recognized tumors of nearly all the tissues of the body—of all, in fact, except the blood-forming tissues. But why should we not have cases of arrested development of cells in the blood-forming tissues, giving rise to conditions analogous to those in recognized tumors? It required but a rapid survey of the pathology and clinical manifestations of the mysterious

anemias to recognize at a glance the analogy of the principle ones among them to the recognized tumors.

We do have tumors of the blood-forming tissues in the following diseases: (1) *pernicious anemia*, where the erythoblastic tissues start to proliferate, and metastases occur to the marrow of the long bones and the lymph glands; (2) *myeloid leukemia* (the classification and terminology are taken from Osler's "Practice of Medicine," edition of 1916), where the tumor process starts in the bone-marrow and metastasizes to the lymph glands, spleen, and other organs of the body in typical tumor fashion; (3) *lymphoid leukemia*, where the proliferation starts in the lymph glands and metastasizes to the skin, etc., and in the special form of *chloroma*, to the skull, orbit, long bones, and viscera generally; (4) *Hodgkin's disease*, where also the process starts in the lymph glands and metastases occur to the spleen, long bones, liver, kidneys, intestines, tonsils, etc.; and (5) possibly other less definite forms of anemia. The *aplastic* type of pernicious anemia presents an interesting contrast, as in this case we have a simple atrophy of the blood-forming tissues as compared with the orgy of irregular and temporarily exuberant cell proliferation which in these other anemias precedes the final degeneration and loss of function, and tends to make the disease longer drawn out. Consider the many irregular types of cell in these anemias, how the growths in some of the leukemias infiltrate neighboring tissues and form metastases; and compare the various types of giant cell with the giant cells of sarcoma, the evidences of toxic action on the system with the tumor cachexias, and the acute form of lymphoid leukemia with the malignant tumors and the intermissions of other forms with the quiescent stages of tumors; also the effects of *x*-ray treatment on tumors and on some of the leukemias. Cabot, writing in Osler's "System of Medicine," states that the *incidence* of certain of the leukemias resembles that of tumors; and, in fact, some investigators have considered some of the leukemias as related to myeloma and sarcoma, and Hodgkin's disease has been confused with lymphosarcoma. But why these mysterious anemias have not all been recognized finally and conclusively as *tumors* of the *blood-forming tissues* is more than I can comprehend, after ance regarding them from this point of view. I suppose the picture presented by the blood itself, with the strikingly irregular shape and structure of the cells, has diverted attention from the true nature of the disease, as in no other tumors do we find the cells swimming around loose in the blood, at least not in noticeable numbers. I believe that it can be necessary only to focus the light of research on these anemias from this angle to get them assigned to their proper place in medicine—with the tumors.

Alas, how little that term "tumor" conveys of the many characteristics and the intricate mechanism of these cellular aberrations If these anemias are really identical with tumors in their nature, they throw an interesting side light on the nature of the tumor process, tending to support my belief that this process is fundamentally an arrest of cell development: for the many *nucleated* red corpuscles in the blood characteristic of these anemias, and especially of pernicious anemia where the red cells are particularly concerned, are obvious cases of arrested cellular development; and the embryonic form of the erythroblastic neoplasms in the marrow of the long bones in this anemia is a case of reversion resulting from arrest of development. Let me make clear just what I mean by arrested development of a cell and reversion. The cells in the lowest strata of epithelial tissues, the cells of gland tissues and connective tissues, and in a general way all the living cells of the body, including, of course, those of the blood-cell-forming tissues, are either constantly multiplying to replace wear and tear, or stand ready to multiply to repair an injury. Of course, this is the case with some tissues more than with others, the muscle and nerve cells, for example, being so highly specialized that they do not retain much if any power of multiplication and regeneration (except from within the cell), and it is significant that tumors occur but rarely in these tissues and are relatively unimportant (unless, indeed, the arrested development, with atavistic reversion, characteristic of some of the insanities be considered analogous to tumors, the changes taking place *within* the nerve cells and being manifested principally by derangement of *function* rather than of *form* and manner of growth; thus senile dementia being essentially similar to the cancer of old age). But in the more actively regenerating tissues the cells either constantly multiply and develop their full tissue functions and characteristics in a highly specialized way, and in close coordination with both their fellow cells of the same tissue, and also with their supporting and nourishing tissues; or else stand in reserve, with their power of multiplication and coordinated development latent, ready to exercise these powers in response to an injury. And if they are overworked by continued irritation, or perhaps injured by chemical, mechanical, or other action (including that of parasites as a possibility), they lose their powers of development into highly specialized normal cells with a coordinated function and revert to a condition that is more primitive or atavistic, characterized by multiplication more rapid and less coordinated with the surrounding normal cells of their tissue, and by their ability to live and multiply when removed from their tissue and transplanted to another in metastasis or in experimental transplantation; and their irregular shapes and sizes and karyokinetic figures and tendency to degeneration show that this reversion is pathological. We must remember that each cell in the body is descended from a unicellular organism, similar perhaps to an ameba; and how much of the ancestral potentialities for living an independent existence remain as a foundation on which are built up the more specialized potentialities for living a highly organized community life with the other cells in the tissues that go to make up the organism, we do not know. That they must retain some of these primitive ancestral qualities we know, because they exhibit them in tumors and in the fact that tissue cells can be kept alive apart from the body, *in vitro*. That they retain all of them is unlikely. Apparently, the latent cells of the tissues stand somewhere between the ancestral free-living unicellular organism and the fully specialized mature tissue cell. They are prob-

ably fully differentiated as cells of their respective tissues, because the cells of tumors can practically always be recognized as belonging to the tissues from which they originate; they are not "embryonic" in the sense of being entirely undifferentiated, like the germ cells; and in an epithelium, for instance, the lower layer cells that regenerate the tissue are obviously not mature epithelial or gland cells. As they move forward from their latent position in reserve to take their places as fully developed cells they undergo a development the stages of which we can in some cases actually see, as, for instance, in a stratified epithelium, losing, no doubt, some or all of their still persisting primitive potentialities and acquiring more specialized ones. Now, if at this time, their development is arrested—if the intracellular mechanism fails, due perhaps to being overworked, or to some mechanical or other injurious influence (it might be just a primary or "accidental" failure of the intracellular mechanism of a single cell, in which case the tumor would consist of the descendants of a single cell, as no doubt some tumors do, as is suggested by the wedge shape of certain epithelial tumors)—they are set loose in a half-baked condition. They are not fully enough developed to fulfill their specialized functions as mature tissue cells, nor do they retain enough of their primitive nature to be able to live as normal unicellular organisms. But they undergo a partial reversion to the atavistic free-living condition, with the results that we see in tumor cells; and their failure to adapt themselves to this mode of life completely is shown by their pathological irregularities of shape and structure and manner of division, and by their degeneration. It may seem strange at first sight that an arrest of cellular development can result in more rapid multiplication of a cell, but when we consider that the normal development of the tissue cell consists essentially in the loss of its primitive generalized powers (and that the power of multiplication is one of the chief among these), and the conversion of these primitive powers into or their replacement by other powers of a more highly specialized nature (the red blood cell, for example, loses even its nucleus), then we realize that more rapid multiplication is to be expected as a result of arrested cellular development, at least until the pathological factors result in degeneration.

North Street and Ward's Lane.

THE ETIOLOGY AND TREATMENT OF "SPANISH INFLUENZA"

By Captain OWEN PAGET, M.D., A.A.M.C.,

Montevideo Camp (Australian), Weymouth, England.

So many theories as to the origin of this disease have been put forward that it may be as well to propose a fresh hypothesis, even though its consideration is still in the early stages. I am the more inclined to do this as such hypothesis adds confirmatory evidence to my theories on tuberculosis, and, in addition, supplies an efficient method of treatment.

In charge here of the tuberculosis wards, I had during the last epidemic of influenzal pneumonia a ward full of the latter cases, in which I was much interested.

My treatment was guided by the recommendations in the medical journals and by my personal experience, and my results were as bad as in other centers. In other words, the patient recovered as a result of his own vitality, which was very little, if at all, enhanced by the treatment he received. Clinically, the seats of infection were—

(1) The tonsils, (2) the lungs, (3) both pharynx and lungs. A case infected in the pharynx alone often recovered within 48 hours, under aspirin.

The expressions of the disease in the lungs were various. Perhaps bronchopneumonia predominated, but true lobar pneumonias and pleurisies occurred.

A very common phenomenon was the absence of physical signs, especially in the early stages. This feature of pneumonia I had noticed many years previously in epidemics of pneumonia occurring in Australia concomitantly with our dust storms. The virulence of this Australian influenzal pneumonia is not high, probably on account of the low vitality of bacterial life there, due to the heat and sunshine and the high vitality of the people, as the result of an open-air life and quantities of nourishing food, especially meat.

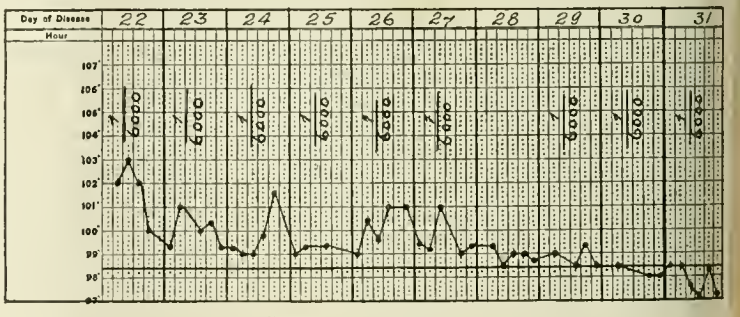

Chart 1.—Private K.

The mortality in these Australian epidemics is quite insignificant, and my researches into the matter were little more than observations. I formulated, however, to myself the possibility that they were epidemics of tuberculosis, and was influenced in this direction by the long subsequent loss of tone in many of the cases.

In spite of the frequency of hemoptysis, the intense virulence of "Spanish influenza" led my mind away from tuberculosis, and I waited patiently for some dictum from the bacteriologists as to what was the invading organism. During this period of vacillation I noticed one point of great interest, namely, that my cases under treatment for tuberculosis were apparently immunized against the influenza. The wards were contiguous, and the easy nature of the Australian made the probabilities of contagion certain. Instead, however, of my tuberculosis patients becoming seriously ill, the few cases affected were of so slight a character as to require at most 48 hours rest in bed; and this at a time when influenza was raging in the camp and attacking the sturdiest with the utmost virulence.

One other point was the complete absence of coryza in patients admitted to hospital with influenza. A cold in the head was apparently some protection against an inflammation of the lung.

Finally, when on leave, I interviewed Messrs.

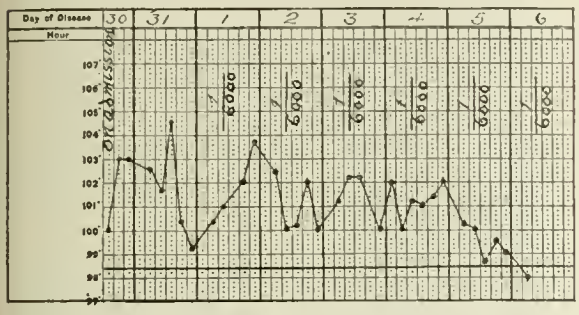

CHART 2.—Private S.

Parke, Davis & Co., with the request that they would prepare me bacillary emulsions of pneumococci, Pfeiffer's bacillus and *Micrococcus catarrhalis* on the same lines as tuberculin B. E. is prepared. This they kindly promised to do, but informed me that it would have to be done in America and that it might be two months or more before I could obtain delivery.

My object in seeking these preparations was to employ them as nasal insufflations on the ethmoid, in the same way as tuberculin B. E. is used by me in the treatment of tuberculosis. In the meantime one of my patients developed a typical hectic temperature, with absence of resolution in the chest. Major Barton, who was called in to see the case, explored with a needle in many places, but could find no pus, and it seemed very probable that the case was one of tuberculosis following influenza. This case (Sergt. H.) was treated by my methods of insufflation of tuberculin B. E. with immediate success. Subsequently tubercle bacilli were found in his sputum in large numbers.

I was so impressed by the result in this case, that the patient (Pte. C.) in the next bed, who was in a condition of partial resolution, was placed under the same treatment and with the same happy result. Unfortunately his sputum was not examined for tubercle bacilli before it had dried up.

My interest aroused by what appeared to be very brilliant results, I still merely regarded these cases as tuberculosis, subsequent on influenza, and I con-

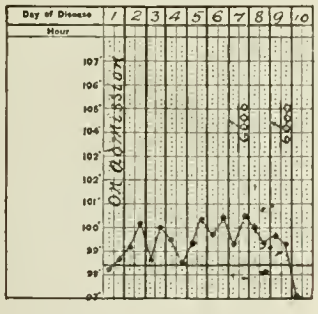

CHART 3.—Private T.

tinued to treat other cases on general lines, determined, however, to employ my own methods if the cases developed seriously. The next case to be treated was later on handed over to Major Barton as an empyema.

By this time I was beginning to suspect that "Spanish influenza" was in reality acute tuberculosis, and I therefore selected two cases with the disease in an acute sthenic form, and both of them patients of robust physique, and therefore not

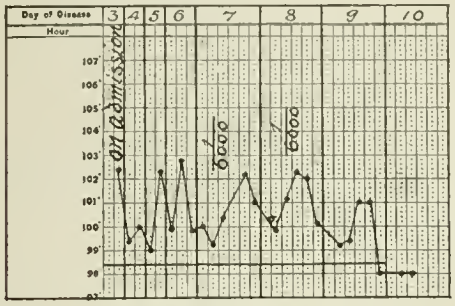

CHART 4.—Private K.

likely to be suffering from previous tuberculous lesions. These cases (Pte. K. and Pte. S.) show in a remarkable manner the beneficial effects of insufflations. Pte. K.'s sputum was found on examination to be full of tubercle bacilli.

In the meantime, Capt. Black, who was now in charge of most of the influenza cases, had sent a patient (Pte. G.) to the tuberculosis ward as a positive case. The effect of insufflations on this patient's temperature was not so well marked, as I intentionally gave him a larger dose, namely 1/500 mgm., than was necessary. To this the little rise in temperature was probably due, although his general condition was distinctly improved. This giving of a larger dose than is directly beneficial is sometimes employed by me to estimate the virulence of the attack. Though it is harmless, when carefully employed, I do not recommend it as a common procedure.

A matter which may be remarked on at this juncture is the extraordinary variation in virulence of tuberculin preparations. They require a true standardization.

During Capt. Black's absence on leave I took over his influenza wards for a couple of days. Selecting the three worst cases (Ptes. T., K., and R.), I placed them on insufflations, with results as shown on the accompanying charts, 3, 4 and 5.

On studying my cases, the mind tends to form the following hypotheses:

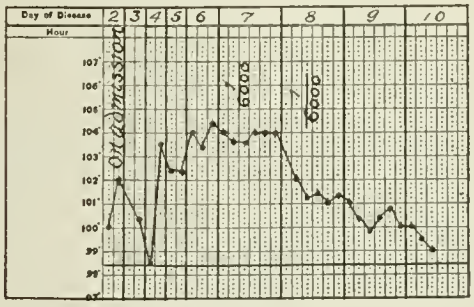

CHART 5.—Private R.

(1) Spanish influenza easily awakens latent tuberculosis. (2) Spanish influenza is an epidemic of acute tuberculosis. Whichever, if either, of these hypotheses is correct, I have no hesitation in saying that insufflations of tuberculin B. E. are a

most potent remedy against this disease, and one I shall always employ in cases which do not show resolution in 48 hours.

It has to be borne in mind that possibly the production of antibody in the ethmoid sinuses can be stimulated by tuberculin bacillary emulsion against some entirely different organism. Conflicting this argument is the abundance of tubercle bacilli found in some of my cases.

A brief résumé of the cases mentioned:

Sgt. H.—On admission, headaches, shivering, and cough. Developed pneumonia right upper lobe; later on right base also affected. Tubercle bacilli in sputum.

Pte. C.—Pneumonia left base; later, pneumonia right base. Nov. 16 aspirated 28 oz. left side; Nov. 30 aspirated 30 oz. same side; Nov. 26, dulness left side much diminished. No sputum for examination.

Pte. G.—Chest clear. No physical signs. Admitted with headache, pains in legs, cough. Tubercle bacilli in sputum.

Pte. K.—Pharyngitis. Scattered crepitations in chest, but no definite physical signs. Tubercle bacilli in sputum.

Pte. S.—Weak breath sounds and crepitations at bases. Free hemoptysis.

Ptes. R., T., and K.—Spanish influenza.

SEBORRHEIC ECZEMA OF THE LOWER LIP, WITH DEEP CENTRAL CRACKING.

By DOUGLASS W. MONTGOMERY, M.D.,

AND

GEORGE D. CULVER, M.D.,

SAN FRANCISCO, CAL.

On June 29, 1918, a stenographer, twenty-four years of age, called on us on account of an affection of the lower lip.

She said that a crack had appeared in it in the present situation eight years previously, and had never perfectly healed.

There was present a deep crack exactly in the median line of the red of the lower lip. This crack extended through the mucous membrane and invaded the cutaneous portion of the lip for a further couple of millimeters. It had rolled edges, but no induration indicating malignancy could be made out. There was scaliness along the whole exposed mucous membrane of the lip just above the mucocutaneous border. The lesion was most annoying. The crack was painful when open, and it would crack open on the least stretching of the lip, as in laughing, so that the patient was constrained to hold the mouth in a peculiar way in order to avoid this accident. This caused a disagreeable alteration of the expression of the whole countenance. It also gave a slightly affected tone to her speech through interference with pronunciation.

The patient was taking too much sugar and too much milk fat, and her occupation as a stenographer caused her to have a meager oxygen intake. She therefore did not burn well these carbohydrates and milk fats, and consequently had a flatulent dyspepsia, which would naturally increase the delicacy of her mucous membranes, and render them more susceptible to infections and to lesions such as cracking.

She slept restlessly, was under weight, and although only twenty-four years of age was rapidly growing gray. She was not constipated, an unusual circumstance with stenographers.

It was concluded that either *x*-rays or radium, because of their action on seborrhoids and on deep, indurative, inflammatory processes, offered the best means of treatment. As the rays of radium are only about half the wave length of *x*-rays, and much more deeply penetrative, it was concluded to use them in preference to *x*-rays. It was also concluded to shield very heavily in order to exclude the longer wave lengths and to secure the deeper action with less superficial reaction.

A normal plaque containing 11 mgm. of radium substance was screened with brass 0.30, aluminum 0.01, and one layer of writing paper, and held in place for half an hour.

A salve was prepared consisting of:

℞ Liq. alumini acetici.....mx
Lanolini
Cerat. simp. āā.....℥ ss.
M., Sig: Apply frequently.

General hygienic and medicinal measures were also taken to improve her health and to increase her resistance, for it may be confidently assumed that these cracks are always infected with streptococci.

By August 13, 1918, the lip was entirely healed, leaving a slight scar in the skin just below the mucous membrane, where the crack had invaded the skin. The expression of guarded tension had not, however, yet left the mouth. Another application of the radium was made, screened in the same way and applied for the same length of time.

By October 14, 1918, the expression of the mouth was normal, and the healing appeared to be perfect.

On the date of this report, February 11, 1919, seven months after the patient first consulted us, and about six months after complete healing, a small scar is still visible where the original crack was, but there are no other objective or subjective symptoms of her trouble.

This seems to us an excellent example of the beneficial effects of radium in these obdurate cases, which are also so dangerous because of their threat of epithelioma.

323 Geary Street.

Grippophobia.—Anglade relates the case of a woman of 40 who developed a phobia concerning the grippe against which she could not possibly react. Despite this fact, the woman had previously shown courage in nursing children with diphtheria. For the past three months or during the period of the epidemic in her vicinity she had no other thought than the existence of the latter and was constantly gargling her throat and spraying her nose. She would not allow any one to approach her. She recovered her mental state, probably after the passage of the epidemic, but it is very likely that it will return with the next outbreak of the same affection, as recurrence of this type has been noted in such cases. Verger stated that nosophobia was apt to be aroused by the pandemic and cited a case in which a case of grippophobia developed in a woman who had once suffered from phthisiophobia. She was a shopkeeper and actually closed her shop for the period of the influenza. Anglade also cited a case of extreme lyssophobia in which the woman finally passed into a state of melancholy with crises of delirium.—*Journal de Médecine de Bordeaux.*

Medicolegal Notes.

Unprofessional Conduct in Prescribing Drugs.—In a proceeding at the instance of the Rhode Island Board of Health for the revocation of a license to practise medicine (which was previously before the court in Knoop v. State Board, 102 atl. 609) twelve witnesses were produced by the State, the majority of whom testified that they had obtained numerous prescriptions for morphine and cocaine from the defendant; that no physical examination of any kind was made by the doctor before prescribing the desired drug; that they stated the amount of morphine which they were accustomed to use, and upon payment of the fee charged they were given a prescription to start with, usually for 60 grains, and were told that they must go for as long a time as possible before returning for another prescription, and that the amount of the prescription would be reduced each time a new one was called for. The wife of one patient was a robust, healthy woman, who did not use drugs at all, but, acting by direction of her husband, she became a patient of the defendant and secured a number of prescriptions of morphine, nominally for her own use, but in reality for the use of her husband and a friend of his. The Rhode Island Supreme Court, on appeal from a decision of the State Board of Health revoking the license, was satisfied that in the case of this woman and in certain other cases no examination of the patient was made before the prescription was given. The so-called treatment of these patients was the same regardless of their physical and mental condition, past history or environment.

"In numerous cases," the court said, "the patients by paying an additional fee secured prescriptions for cocaine also. The excuse for using this given by the patient was that the cocaine relieved the pain caused by the needle when the morphine injection was taken. The appellant says that the cocaine was prescribed in one case for neuralgia or neuritis, and in other cases to relieve the patients from constipation, one of the common results of drug using. Neither explanation is convincing. The patient undoubtedly wanted the cocaine to satisfy the craving for drugs. The cocaine habit is as well recognized by the medical profession as the morphine habit, and, as stated by one of the medical witnesses in regard to this particular subject, it does not seem fair for the sake of relieving the ailments above mentioned to take the risk of fastening an added drug habit upon a patient who is already a victim of the morphine habit. Whenever a cocaine prescription was written an extra charge, usually $1, was made in addition to the customary charge of $2.

"The appellant claimed that the treatment given to these patients was given in good faith and in accordance with recognized medical practice of 'cure by reduction.' Testimony was given in regard to this form of treatment to show that the method was to decrease regularly and continuously the amount of the drug taken by the patient and to deprive the patient of the drug entirely as soon as feasible. It appears that this method has been used with more or less success when applied in institutions where the patient was under the constant observation and continued control of the physician, when the amount of each dose could be regulated by the physician and not by the patient, and that in some cases it had been used with success outside of an institution when the patient was possessed of strong will power and a fixed determination to be cured, but, if the patient was lacking either in the necessary will power or the desire to be cured, that this treatment would be of no avail. One of the physicians who testified on behalf of the appellant testified very frankly that he would not undertake the treatment outside of an institution of an addict who did not desire to be cured, for the obvious reason that it would be useless.

"In the case at bar the appellant continued to treat a number of these addicts when he knew, according to his own testimony, that they did not desire to be cured, that they were getting drugs from other sources in addition to the amount prescribed by him and had secured prescriptions for additional amounts from him on their false statements that they had lost a part of their weekly supply. . . . That he [the appellant] did not expect to cure his patients is made clear by his own testimony, when he was recalled to the witness stand after other witnesses had testified in regard to his method of treatment. The appellant then admitted that he did not expect to cure his patients, that the only practical way of effecting a cure would be by placing them under control in some institution, and that his object was to give his patients a sufficient supply of the drug to enable them to continue their usual occupations.

"This particular testimony requires no extended comment. Such treatment for such an avowed purpose is illegal and unprofessional. One of the objects of the Statute (Chapter 178 of the Gen. Laws, 1909) is to prevent drug addicts from securing the desired drug and thereby enabling them to continue the drug habit. The Legislature recognized the necessity of making some provision for these unfortunate people and in a proper case permitted physicians to prescribe morphine, etc. Such treatment, however, must be in accordance with the recognized practice of medicine, the object of which, in cases wherever it is possible, is to effect a cure.

"The procedure followed by the appellant neither cured the patient nor was it adapted to cure him. So long as the patient was able to procure his supply of the drug he would remain a drug addict. The treatment of the appellant was directed principally with the purpose of securing the fees which his patients paid to him in order to secure the desired prescription, and the conclusion from the testimony is irresistible that whatever reductions were made in the amount of the drug prescribed were due more to a desire on the part of the appellant to escape a prosecution for violation of the law than to any expectation on his part of effecting a cure of said patients, or of securing for his patients any permanent benefit." The finding of the State Board of Health revoking the appellant's certificate was affirmed.—Knoop v. State Board of Health, Rhode Island Supreme Court, 103 Atl. 904.

Expert Opinion.—In an action for injuries to a child a medical expert testified that "the skull consists of two tables of bone, with a spongy bone between the two, and sometimes a fracture may extend further on the inside than it does on the outside. Of course a fracture of that kind cannot be seen." This was objected to as regards what might possibly be underneath, the objection being to the witness testifying to anything he did not know. The answer was held to be clearly within the realm of proper expert testimony, and if it were otherwise the error was rendered harmless by the witness' subsequent assurance that he did not know whether or not the fracture extended into the motor area of the brain.—Ahouen v. Hryszko, Oregon Supreme Court, 175 Pac. 616.

Liability of Private Hospitals.—In an action against a private hospital by a patient for damages because of pneumonia, alleged to have been caused by a heavy rain penetrating a leaking roof, the Oklahoma Supreme Court holds that the rule is well settled that, when a hospital is being conducted for private gain, it is bound to exercise that degree of care toward its patients, measured by the capacity of such persons to look after and provide for their own safety, as an ordinarily prudent person would exercise under like circumstances and conditions. The rule laid down in Hogan v. Clarksburg Hospital Co., 63 W. Va. 84, 59 S. E. 943, is as follows:

"There can be no question about the liability of a hospital which is being conducted for private gain and not for charitable purposes, for damages to its patients through the negligence of its officers and employees. . . . It is the duty of such hospital to employ only competent physicians and nurses, and to treat such patients with such skill and care as ordinarily obtains in the conduct of such institutions, and to protect its patients in such manner as their condition may render necessary, and such degree of care and diligence should be in proportion to the physical or mental ailments of the patient rendering him unable to look after his own safety."—Tulsa Hospital Assn. v. Juby (Okla.), 175 Pac. 519.

Military Medicine.

Sanitary Aspects of Warfare in Southeastern Europe.—The war now practically over, in spite of the immense size of the armies engaged and of the magnitude of the operations conceived and carried out, has been distinguished from the medical point of view perhaps chiefly by the triumphs of preventive medicine. However, this statement must be made with a certain amount of reserve. While it is absolutely true that disease on a large scale was successfully prevented on the Western Front, with the exception possibly of influenza, on the Eastern Front prophylaxis was less satisfactory. The Russian and Serbian armies were decimated by disease and even the French and British armies in the near East and in Southeastern Europe were, at one time, and at a somewhat critical time too, almost incapacitated by diseases of various kinds, mainly insect borne. It must be borne in mind that the part of Southeastern Europe in which the Anglo-French armies were stationed is notoriously unhealthy. A large portion of it is infested with mosquitos and rife with malaria. At the time of the coming of the Western forces drainage of the large areas of swampy lands was lacking and in addition to anopheles mosquitos various other insects abounded. The inhabitants lived in an extremely primitive way, sharing their houses with their fowls, pigs, cattle, and horses, the consequence being that lice, flees, and bedbugs were almost as numerous as the sands of the sea shore.

Professor W. J. R. Simpson, writing regarding sanitary conditions in Southeastern Europe during the war, in the *Transactions of the Society of Tropical Medicine and Hygiene* for October, 1918, gives a vivid account of the difficulties with which the British medical corps had to cope in Macedonia. As for the domestic insect pest, he states that many of the patients admitted to hospital, sometimes suffering from malaria, were so abundantly covered with flea-rash that unless carefully examined the impression was conveyed that they were typhus fever cases. The water supply in many places, especially in those near the foot of the hills, is good, owing to its origin from springs, but wherever there are wells, they are polluted with filth; canteens, kitchens, and wells are usually close together. There is much dysentery among the civil population, both bacillary and amebic, the former being the most prevalent, but the two diseases which bulk the largest are malaria and tuberculosis.

By the time Monastir was taken by the Serbs and French in November, 1916, and the British were fighting in the Struma Valley, the toll of sickness from malaria, sand-fly fever, and dysentery had been enormous. The British troops, perhaps, suffered in a less degree than the French, except in the Struma Valley, where all the regiments were more or less affected, some worse than others. It is not surprising that the name which the allied armies received was the "Phantom Army." For example, a regiment entered the Struma Valley 900 strong. In six weeks there were only 200 left not in hospital.

The paper by Simpson shows clearly that Southeastern Europe is an unhealthy area for warlike operations, and that though disease has fallen very heavily on the armies of these countries who do not pay the same attention to hygiene that the British pay, yet in this war the Gallipoli and Salonica experiences demonstrated that the sanitary organization and measures which have been so effective in France have not been sufficient for armies operating in countries where malaria exists, and where the sanitation is in a very primitive condition. This state of affairs as regards the preventive side of disease in the British armies, as distinguished from the hospital and curative side, is emphasized also by what happened in Mesopotamia and Egypt. It appears to Simpson that the British sanitary service for campaigns in tropical and sub-tropical countries must be submitted to a thorough examination and be reorganized on a very different basis. These views, he thinks, can be held without in any way diminishing the importance and magnitude of the work done by the British sanitary service in France. The results are written large in the health conditions of the army there. The reason for Simpson's views is that the conditions under which the armies were operating were different, so that what was found adequate for the West was not so for the East nor for the Tropics.

The chief requisite of efficient sanitation and hygiene in tropical and sub-tropical climates is first and foremost to eradicate the insect pest so far as is possible. So long as insects, the hosts and conveyors of many diseases, abound, just so long will these diseases flourish. While the eradication of insects on a wide scale is the most important step in the direction of conquering tropical diseases, another essential movement forward is to improve sanitation, and domestic hygiene in particular, in tropical countries. The war in the East has shown what can be effected by judicious sanitary and hygienic measures and the knowledge there gained should be put into practice wherever necessary.

Health of the Army.—According to the statistics made public on February 13, there are about 82,539 sick and injured soldiers remaining overseas. Of these 19,966 were listed as suffering from injury and 62,573 from disease. This was a reduction of about 60 per cent. as compared with the figures of November 14, 1918. A report from the War Department, Washington, under date of March 7, states that the health of the troops in the camps of this country continues very good. A recrudescence of influenza and pneumonia was noted at Camp Taylor, Ky. It is also announced that the crest of the tide of returning sick and wounded soldiers has been passed. The War Department has tried consistently to send the sick and wounded to hospitals as near their homes as possible but the requirements for proper hospital attention have made the situation difficult and many men have had to be retained at debarkation hospitals in or near New York.

Doctors Consult by Wireless.—Physicians on the transports *Sierra* and *Powhatan*, which reached the port of New York on March 6, held a consultation by wireless telephone while the ves-

sels were fifteen miles apart at sea in regard to influenza cases on the *Powhatan*. Lieut. Commander A. E. Younie, senior surgeon on the *Sierra*, also diagnosed the ailment and prescribed treatment by wireless telegraph for a sick man on the British steamship *Pollac* which was one hundred miles distant. Lieutenant Commander Younie is reported as saying that the wireless telephone opens a wide field for the medical profession, since most ships of our merchant marine will not carry surgeons but the capitain of such a vessel will always be able to obtain medical services either from shore or from some other ship.

Army Quits Long Beach Hotel.—Army General Hospital No. 39, at Hotel Nassau, Long Beach, L. I., is to be abandoned. Surgeon General Ireland announces that the institution will be cleared of patients and personnel by March 15.

Many Disabled War Veterans Take Vocational Training.—The Federal Board for Vocational Education, in a report on its activities for 1918, shows that 12,000 American soldiers, sailors, and marines, disabled in the war, have been registered as prospective candidates for vocational education.

Many Sick and Wounded Reach Port.—During the week ending March 8 some eleven troopships reached New York, bringing an influx of 4,100 sick and wounded. On the *Leviathan* there were nine convalescent detachments, comprising 1,179 war victims in charge of 56 nurses. The *Santa Marta* from Brest brought forty-five medical officers and thirty-five nurses, among whom were included a number of the members of the Mount Sinai (New York) Hospital Unit.

First Lieut. Abraham F. Thomas, of Newburyport, Mass., attached to Ambulance Company No. 1, Second Division of the Regular Army, A.E.F., has been awarded the **Croix de Guerre** for distinguished service in the face of the enemy during the battle of Blanc Mont Champagne sector from October 1 to 10, 1918.

Capt. Conrad Wesselhoeft, M.C., U. S. Army, of Boston, attached to the 104th Infantry, was awarded the distinguished service cross and also the **Croix de Guerre** for his services in caring for the wounded under fire.

Hospital Units to Return.—An announcement made by the War Department on March 3 states that Base Hospitals Nos. 11, 34, 38, 52, and 58, Convalescent Camp No. 2, and Evacuation Hospitals Nos. 2 and 4 have been assigned to early convoy.

Deaths in the Service.—Lieut. Edward Sartor Stewart, M.C., U. S. Army, of Summertown, Tenn., a graduate of Vanderbilt University, Nashville, in 1911, died at Camp Greenleaf, Ga., from lobar pneumonia, on October 13, 1918, aged 32 years.

Lieut. Ralph Edgar Powers, M. C., U. S. Army, of Akron, Ohio, a graduate of the Eclectic Medical Institute, Cincinnati, in 1915, died from wounds received in action while on duty with the American Expeditionary Forces on January 22, aged 28 years.

Capt. Gilchrist Briggs of the American Volunteer Ambulance Corps, died, on March 2, at his home in Schenectady, N. Y., aged 54 years. He was graduated from the Albany (N. Y.) Medical College, in 1889, and during the war served with both the British and French armies. He was awarded the Croix de Guerre for removing French wounded from the zone of fire during the battle of Verdun.

Capt. John D. Hess, M.C., U. S. Army, of Clarkton, Mo., a graduate of Washington University, St. Louis, in 1900, died from pneumonia while on duty at Fort Bliss, Texas, on October 17, 1918, aged 41 years.

Major Joseph James Kinyoun, M.C., U. S. Army, of Washington, D. C., a graduate of Bellevue Hospital Medical College, in 1882, died of lymphosarcoma of the neck at his home in Washington, on February 14, aged 58 years. He was a surgeon in the U. S. Marine Hospital Service from 1886 to 1902, professor of hygiene and bacteriology from 1890 to 1892, and of pathology and bacteriology from 1892 to 1899 in Georgetown University, Washington, D. C. He was decorated with the Order of Bolivar in 1897 on account of his excellent sanitary services to the Republic of Venezuela. He was a member of the Association of American Physicians, the Association of American Bacteriologists, and American Public Health Department of the District of Columbia. He was founder and first director of the United States Hygienic Laboratory, and director of the H. K. Mulford Laboratories from 1902 to 1907. He was on duty at the cantonments of North and South Carolina until December 6, 1918, when he was detailed as pathologist to the Army Medical Museum.

Capt. James Williamson Squires, M.C., U. S. Army, of Charlotte, N. C., a graduate of the North Carolina Medical College, Charlotte, N. C., in 1911, died from lobar pneumonia in the U. S. General Hospital at Toul, France, on December 16, 1918, aged 30 years. He was professor of rectal diseases in his alma mater.

Capt. Aaron Shiner Oberly, Med. Dir., U. S. Navy, retired, of Avon, Conn., a graduate of the Medical Department of Yale University, in 1860, died at his home, on February 15, aged 81 years. He entered the Navy in July, 1861, serving throughout the Civil War. He was made chief surgeon of the Adriatic in 1886 and was retired after ten years and six months sea service, on January 4, 1889.

Lieut. Bedford Wagoner Russell, M.C., U. S. Army, of Strong City, Okla., a graduate of the Epworth College of Medicine, Oklahoma City in 1909, on duty at Fort Riley, Kan., died from the effects of influenza at the home of his mother in Oklahoma City, on February 13, aged 31 years.

Major Clarence Ewen, M. C., U. S. Army (retired), a graduate of Bellevue Hospital Medical College in 1862, died at his home in Washington, D. C., on January 6, aged 75 years. He was assistant surgeon of the New York State Volunteers in 1862; assistant surgeon of the 102d United States Volunteers in 1862 and 1863; acting assistant surgeon, United States Army, in 1864; assistant surgeon of the United States colored troops in 1864 and 1865; and acting assistant surgeon, United States Army, in 1868. He was promoted to major in 1889, and was retired at his own request after thirty years of service.

MEDICAL RECORD.

New York, March 15, 1919.

EPIDEMIC INFLUENZAL ENCEPHALITIS.

THE occurrence in Chicago of some cases of narcolepsy or lethargic encephalitis, which the newspapers call "sleeping sickness," dependent upon influenza, was doubtless to many the first intimation that encephalitis is a known complication or sequel of the grippe. The claim that this affection occurs with or in the wake of the influenza epidemic has indeed been made, but such disease association does not apparently manifest itself in all countries ravaged by the latter. Nor does encephalitis occurring in the course of infections always impose itself as a lethargic affection. Polioencephalitis, in general, may or may not be associated with narcoleptic crises and somnolence. There is evidence that the study of this clinical and pathological entity may possibly lead to the discovery of a new nervous center, which, when implicated in an infection, or even functional disturbance, may cause phenomena which suggest narcolepsy, sleeping sickness, catalepsy, or other clinical syndromes.

Molinari, writing in *La Riforma Medica* for February 1, asks two questions which he seeks to answer: "Is this affection new?" and "Is it autonomous?" In regard to the first query, he refers to the affection known as "noma," which followed in the wake of the pandemic in 1889-90. In the spring of 1890 the newspapers of the Continent were filled with reports of a new disease called noma, or sleeping sickness, which had broken out in Italy, and which it was feared would invade the rest of Europe. It was soon recognized as a comatose form of influenza, and it was subsequently traced through a large part of Europe, and even reached the United States. An epidemic of "sleeping sickness" swept Europe in 1740, in the short interval between two visitations of the grippe, and may readily have been connected with cases left over from the 1737 epidemic. In 1900, Bozzolo found two sporadic cases in Italy which paralleled closely the sleeping sickness of the African negro, but careful study showed that it was presumably affiliated with influenza, at that time, of course, only endemic.

In regard to the question of autonomy, it was at first regarded as a not fully developed form of cerebrospinal meningitis, and it is even now found very difficult to distinguish the affection from the encephalic form of acute anterior poliomyelitis, which has a protean sweep of clinical manifestations. Authorities like Netter, however, remain dualists. Another problem is the connection, if any, between infection of the rhinopharynx and encephalitis.

THE PRACTITIONER OF THE FUTURE.

IN the past decade there have been signs of impending change in the science and art of medicine. Drug therapy has been subjected to a good deal of criticism and ideas as to the value of drugs have undergone more or less revision. This alteration in the attitude of a goodly proportion of the medical profession was due, to some extent, to the manner in which drugs, most often of German origin, were continually being brought out for the treatment of every kind of disease, but was owing more largely to the fact that despite advances in pharmacological knowledge, medical men were conscious that many drugs were given without any certainty as to their value and without definite knowledge of their mode of action. While there are not a few drugs which by the test of experience have shown themselves to be of therapeutic value and of which little is otherwise known, there are many new drugs of which little is known concerning either their mode of action or their value. When long experience has demonstrated the usefulness of a drug, it is right to recommend it, even if the why and wherefore of its action are not known. On the other hand, when knowledge is lacking as to why a drug acts as it does act and when it has not come through the clinical test with satisfaction, then it seems assuredly wise either to discard such a drug or not to recommend it until further investigation has proven its efficiency.

However, the drug problem, that is, to know what kind of drug to give and when, is not the only one that confronts the medical profession and calls, if possible, for solution. It must be borne in mind that the methods of practising have changed vastly during the past fifty years. This is the age of the specialist and of laboratory research. With regard to laboratory research, Sir James Mackenzie, writing in Vol. 1 of "Oxford Medicine" on the future of medicine, points out that the methods of investigation and the type of individual who prosecutes research have altered during the past fifty years. Before that time the investigator was a man engaged in medical practice, who, recognizing in his patients problems that needed solving, sought their solution by experiments conducted by himself or under his supervision. This was the method pursued by such men as Harvey, Hunter, Jenner, and Lister. All this has been changed and research work has passed almost wholly into the hands of the laboratory worker, and to laboratories are attracted many of the most brilliant and able of the younger members of the medical profession. The view is becoming crystallized that by laboratory work alone can medical research be advanced and thus other means of investigation are ignored.

Mackenzie, while acknowledging that laboratory investigation has done great service in forwarding the progress of medicine, is yet convinced that the method possesses certain inherent defects. He is of the opinion that underlying all the seemingly reasonable belief in laboratory research there exists a fallacy. Investigators are now specially trained for their work under men who have spent their lives in the laboratory. Consequently the pursuit of knowledge tends to assume ever more and more an academic character, with little reference to the problems confronting the doctor who practises medicine. This is in contrast with the methods pursued by the great pioneers whose names are mentioned above. Laboratory workers now get a limited view of disease, and it must be recognized that their opportunities permit them to see but a very small part of the field of medicine. This is to say that the pure laboratory investigator is merely an investigator and nothing more. The old time investigator was generally a man in general practice, as Jenner, for instance, or as Mackenzie himself, who was deeply skilled in clinical diagnosis and learned to investigate with human material and in a field far wider than the up-to-date highly scientific investigator. The results, too, were eminently satisfactory.

Moreover, as Mackenzie shows, the reaction of these views upon medical practice is seen in the breaking up of clinical medicine into a series of specialities. Diagnosis of any case which appears to be at all out of the common is not now attempted by one man but a number of specialists. The patient may be sent from one consultant to another, each of whom sends in a report dealing with the organ or method in which he specializes, and then the original physician studies these reports and is supposed to be in a position to treat the case properly. The method is impressive, and, needless to say, costly, but in reality there is more than one rift in the lute. In the first place, it is almost out of the reach of all but the wealthy, and even if institutions under government were started only a limited number of persons could be treated.

The most damaging criticism that Mackenzie directs against the ultra specialist institutional system of dealing with disease is that the cases in the early stages would not be sent, and, if sent, their ailments would probably not be recognized, for the phenomena created by the early stage of the disease are not revealed by mechanical means or laboratory methods.

The point must never be lost sight of that the effect of disease is rarely limited to one organ; in many cases the change in one organ is secondary to conditions elsewhere. Some specialists whose horizon is restricted to their particular subject are not always capable of recognizing the remote causes and effects. Also, the physician whom the patient first consulted, implied by the very fact that he had to call in help that he was not able to detect the phenomena produced by the disease, and, as Mackenzie pertinently asks, if he was not capable of finding them, how could he be qualified to assess their value?

The writer enters somewhat fully into the question, and emphasizes the need of an urgent call to the clinical investigator to view his position from a standpoint different from that to which he has been accustomed There is a great field still unexplored for the detection and for the assessment of the value of symptoms recognizable by the unaided senses, or by simple mechanical aids. The class of investigators must be enlarged to include those who have the opportunities of seeing disease in its earliest stages, and the clinician must take a part in the laboratory investigations in order to solve the numerous problems that will arise if he sets himself to find out the significance of the signs of the disease. In the medicine of the future, the laboratory investigator, pure and simple, will not hold the predominant position he now holds, if the advice of this British investigator is ever followed. Indeed, his importance will be subordinated to that of the clinician who interests himself in laboratory investigations. Neither will the specialist reign as supreme as he reigns at the present time. Both the laboratory investigator and the specialist will, of course, play their part, but the all-round man of practical experience will surely come into his own again.

THE PATHOLOGY OF CHELOID ACNE OF THE NECK.

Cheloid acne has been described by Lenoir and Vidal as a pilosebaceous perifolliculitis with a cheloid tendency, the structures surrounding the follicles tending to the formation of a sclerous tissue instead of progressing to suppuration as in ordinary folliculitis. Some time later, Dubreuilh described the presence of giant cells. The lesions commence first in the sebaceous gland, the cells of which assume the aspect of giant cells, and secondarily, the lesions progressively extend and end in the formation of a follicular abscess. Therefore, originally the lesion is an acne and not a folliculitis, since the first lesions arise in the sebaceous gland, which is totally destroyed before the follicle becomes involved. The perifolliculitis secondarily provokes suppuration of the follicle on the one hand and a cheloid on the other. Dubreuilh also admits that cheloid and cheloid acne have both the same structure and are differentiated only by their respective evolutions; a true cheloid being a proliferating new growth, cheloid acne on the contrary always following an acne.

Mibelli maintains that the lesions commence by small follicular abscesses, and the presence of giant cells in the sebaceous glands should prove, on the contrary, that this lesion is secondary to the precedent. At the same time, a cell proliferation occurs around the vessels of the dermis, ending in the formation of cheloid nuclei under the influence of some pathogenic agent as yet to be determined, as well as by lesions resulting from the friction of the

clothing. Ledermann and Ullman have described the presence of eosinophile cells and certain formations which they term Russell's corpuscles. Mantegazza has mentioned the presence of plasma cells along with giant cells, while Baillon describes cheloid acne as a subacute or chronic nodular inflammation which is similar in nature to a certain number of bacterial affections, particularly tuberculosis.

Quite recently, Gouin distinctly separates cheloid plaques still presenting small active "pustulettes," which he calls "inhabited" cheloids, from adult cheloid offering no trace of infection and found in the center of the "inhabited" cheloid plaques. After having studied the pathology obtained from biopsies of four patients, Gouin and Pautrier come to the following conclusions: The areas still in activity which contain "pustulettes," and which may be looked upon as the extension zone of cheloid formations, present two types of lesions, namely, those of the pilosebaceous system and those of the intervening dermis. At certain spots the pilosebaceous lesions offer the aspect of simple folliculitis and perifolliculitis with a tendency to suppuration, but giant cells are also to be found. At other points the entire sebaceous gland is transformed into a mass of giant cells which destroy the infiltrated hair. In the intervals between these foci of pilosebaceous lesions, examination shows that the dermis is sclerosed and forms meshes filled with foci of infiltration almost exclusively composed of plasma cells, although giant cells may also occasionally be present.

As the evolution progresses the cheloid assumes a different aspect. The pilosebaceous system and even the giant cells disappear and there remains an almost pure plasmoma riddled by a sclerosed connective-tissue stroma. Regardless of the opinion maintained by Dubreuilh, Gouin supposes that the pathogenic agent penetrates in the first place into the pilosebaceous orifice and there sets up the formation of a pure folliculitis. At this phase of the process suppuration may sometimes occur; later on, either on account of the chronicity of the lesions or because of the low virulence of the pathogenic agent, a slow process of inflammation becomes established around the follicle, which ends in the formation of giant cells. This process reacts on the sebaceous gland and then sets up the production of giant cells within it. What would seem to prove that the evolution of the process takes place as described is that at this last phase the hair is completely destroyed and only the lesions of the dermis persist.

The differentiation of true cheloid from cheloid acne is to be made from the fact that in the adult stage the former process has the structure of a fibrous growth composed of fibrous connective tissue, containing only fixed connective-tissue cells and no trace of foci or infiltration. In cheloid acne, on the contrary, even at the stage of complete development, numerous plasmomata are always found.

Peace-time Surgery.

Undoubtedly many surgical lessons have been learned from the war and consequently a considerable amount of progress has been made, but it may be well to point out that war surgery is in many respects a very different affair from surgery in civil life and that experience of war surgery does not fully equip the surgeon for dealing with the surgery of civil practice. The man who has been operating day after day for three or four years in base hospitals and casualty clearing stations, is not necessarily on account of his wide experience at all times competent as an operator in civil practice. As a matter of fact, although this statement is obvious, conditions from the surgical outlook are so different in civil life that the surgeon versed in army methods will have to revise his modes of procedure considerably in order to adapt himself to civil practice. The fear has been expressed that with the return of surgeons from the seat of war, of men who have acquired great manual dexterity and who have become accustomed to the manner of operating in war hospitals, an orgy of operating will set in. Mr. C. Hamilton Whiteford, writing in the *Medical Press* for January 29, voices this view and lays down a list of surgical "don'ts," presumably for the behoof of surgeons habituated to the customs of army medical practice. These don'ts appear to be to the point and especially those which lay emphasis on the need for an aseptic environment when operating. Whiteford contends that in no circumstances should an operation be performed in a patient's house, and undoubtedly such advice is fundamentally sound, though not always practical. It is true that many valuable surgical lessons have been taught by the war, lessons which will prove of the greatest use in civil practice. Nevertheless it is timely to draw attention to the fact that peace conditions differ widely from war conditions and that this applies with equal force to peace surgery and war surgery. The progress made in surgery during the war must be adapted to meet civil conditions and not to override them.

Mortality in Madrid During the Grippe Year.

According to *La Medicina Ibera* for January 4, the total number of inhabitants of Madrid is at present approximately 624,303. The number of births in 1918 was 16,672, and that of deaths 18,961. The total deaths in 1917 were 15,557. It is thus clearly shown that the balance is on the wrong side of the ledger. This is due to some extent to the prevalence of variola in 1918, which disease caused 431 deaths. It is, of course, only too evident that the chief agent in reversing the vital statistics is influenza, but to bring out the full participation of the latter we must also enumerate all of the acute respiratory disorders. The deaths set down to grippe alone are 954. The number of deaths from acute bronchitis is given as 908, which should include some bronchopneumonias. The pneumonias *per se* add up to 549 only. There are, however, nearly 2000 cases of respiratory affections in which apparently no diagnosis was made. The author gives the causes of increased mortality as smallpox, bronchopneumonia, and grippe. Since chronic respiratory diseases are abundantly accounted for, we have over

4,000 presumably acute pulmonary affections which proved fatal. It is hardly to be doubted that influenza at least trebled the normal death rate of these affections. Despite the vagueness of these figures it seems that Madrid, as the first great center of population attacked, reaped some slight benefits from the mildness of the initial outbreak and the protection afforded against recrudescences. The figures cited cover a calendar year, including the cold-weather mortality of the first months of 1918, while influenza raged in the last two-thirds of the year. Nevertheless, an increase in the deaths in one year of 3,404, of which only a fraction could be attributed to other causes, seems to speak eloquently of the deadliness of the pandemic.

News of the Week.

Another Medical College Will Admit Women.—At the commencement exercises of the New York University and Bellevue Hospital Medical College on March 3, Chancellor Brown announced that for the first time in its history this institution will admit women on the same basis as men with full privileges of the college and will grant them the degree of doctor of medicine upon graduation. Degrees were conferred at this time upon seventy students who finished their medical course three months earlier than usual owing to the war emergency program adopted last year.

Typhus Fever in Germany.—A despatch to the Associated Press, under date of March 1, states that within the week the number of cases of typhus fever in Germany rose from 144 to over 500. Of these 18 cases were reported in Berlin. It is believed that the disease was brought to Germany by troops and civilians returning from Russia.

Mount Sinai Hospital Report.—At the annual meeting of the Society of the Mount Sinai Hospital, New York, on February 3, it was announced that the construction program arranged before the war would be resumed at the earliest possible date. It is expected that the actual work on the new buildings will be begun in the spring of 1920 and that the buildings will be complete before the end of the following year. Colonel Howard Liliental, in charge of Base Hospital No. 3, the Mount Sinai Unit in France, and Major Edwin Beer told of their work in France. The unit had a very active service as many as 2,800 patients being taken care of at one time. The expenses of the hospital for the year were $652,835, and were covered by receipts of a similar amount, $213,388 of which was contributed by the Federation of Jewish Philanthropies. It was also reported that the experimental stage of the Cardiac Section had been passed and it had been regularly incorporated as a part of the dispensary and had been installed in quarters especially designed for it in the Children's Clinic.

Rockefeller Money for Medical Education.—At a meeting of the General Educational Board of the Rockefeller Foundation, appropriations of $1,108,525 were made to carry on the work of various educational institutions throughout the United States, the largest amounts being given for the furtherance of medical education. Johns Hopkins Medical School received $400,000 for the endowment of a department of obstetrics and the Meharry Medical College, Nashville, Tenn., for negroes, received $150,000.

Influenza in Japan.—According to the report of the Home Department officials there were in Japan during the months of October, November, and December 10,000,000 cases of influenza. This means that about one in every seven of the population has been attacked. During the three months about 80 per cent. of all deaths were from influenza.

Bolsheviki Kill Incurables.—A despatch from Stockholm reports that typhoid fever is raging with increased force in Petrograd. In one hospital 8,000 patients are said to be dying monthly. In the provinces the mortality from the disease is so high that the Bolsheviki have issued a secret order to kill the incurable cases, hoping thus to stop the spread of the contagion in some measure. Scarcely any medicine is available.

Sing-Sing Prison under Quarantine.—An epidemic of diphtheria has broken out in Sing-Sing Prison, there being forty prisoners down with the disease on March 6. An embargo has been placed on the movement of prisoners both coming in and going out. It is believed that the epidemic is now on the wane.

Poliomyelitis After-Cure.—The January *Bulletin* of the New York State Department of Health gives an outline of the work the State Board of Health is doing in caring for poliomyelitis victims. During 1918, 42 clinics have been held in 53 municipalities. The total number of cases examined was 654; of this number 456 had attended previous clinics and had been under the care of field nurses. Forty-nine were discharged cured, or practically normal, and 296 were improved, the improvement consisting in increased strength of the weak or paralyzed muscles or a general improvement. During 1918, 823 pieces of apparatus were delivered to patients. Eighty-three patients have been admitted to various hospitals for operations or for the correction of long standing deformities. The results in these cases have been very satisfactory. There were about 70 new cases of the poliomyelitis during the year and these are now being visited by the nurses and after-care treatment begun as soon as the acute symptoms have subsided.

Druggists Object to Selling Liquor.—Representatives of the New York State Pharmacists' Association appeared before the Senate Judiciary Committee on March 5 to protest against any provision of the proposed prohibition enforcement law which will permit them to handle liquor. They urge that the medical men who want to prescribe liquor in certain cases should dispense as well as prescribe it and not throw that burden on the drug business. The druggists want to be permitted, under special permit, to purchase alcohol for prescription purposes only and not to be used for beverage.

Drug Clerks Form Union.—The drug clerks of New York City have organized a union called the "United Drug Clerks' Local No. 325, and have appealed through a resolution to the Central Federated Union for its assistance toward bringing

about amended legislation that will lessen their working hours. At present they are required to work 132 hours a week, which makes, including the lunch hour, a twelve hour day. They also believe their wage scale should be higher; on an average they are now paid $25 weekly.

New York's Drug Addicts.—James A. Hamilton, Commissioner of Corrections, in his anual report on drug addicts, urged that the idenities of such persons be admitted to public record. He reported that during the year 240 men and 32 women were committed by the courts as drug users, of whom 114 men and 16 women had never been convicted before. Mr. Hamilton recommends that all drug users be committed to a correctional institution instead of to hospitals for treatment, because it is too easy to get out of the latter.

Dr. Frederic Huntington Coerr, who has just returned from foreign service, has resumed his practice at 8 East 54th Street, New York City.

Lieut. J. C. Barker, formerly an interne at the New Haven Hospital, has been awarded the medaille sauvetage presented by the Minister of the Interior of France for his work in France during the recent epidemic of influenza. This is a civil and not a military decoration and Lieut. Barker is one of the first medical men in this country to have received this award.

Dr. Cecil Gaston, recently returned from service in the Medical Corps of the U. S. Army, has been reinstated to the position of City Surgeon of Birmingham, Ala.

Board of Health Requires Whooping Cough Arm Band.—The Board of Health of Hornell, N. Y., has adopted whooping cough regulations requiring the placarding of houses and the exclusion of persons not immune to the disease. The person is allowed the liberty of the yard provided he avoids contact with non-immunes and wears an arm band with the words "whooping cough" printed in red ink.

The Medical Association of the Greater City of New York.—A stated meeting of this association will be held at the New York Academy of Medicine on Monday, March 17, at 8.30 P. M. Papers on Chronic Intestinal Toxemia will be read by Drs. A. A. Rutz of Brooklyn and J. G. Dwyer of Manhattan, and will be discussed by Drs. E. Libman, Helen Baldwin, H. F. Graham, and others.

American Medical Editors' Association.—The fiftieth annual meeting of this association will be held at the Marlborough-Blenheim Hotel, Atlantic City, on Monday and Tuesday, June 9 and 10. An attractive program is now being prepared, and all physicians even remotely interested in medical journalism are invited to attend.

Medical Society Elections. — The TRI-STATE MEDICAL ASSOCIATION, which met in Richmond, Va., on February 18-19, 1919, elected the following officers for the ensuing year: *President,* Dr. Robert C. Bryan, Richmond, Va.; *vice-president for Virginia,* Dr. Clifton M. Miller; *vice-president for North Carolina,* Dr. A. J. Crowell, Charlotte; *vice-president for South Carolina,* Dr. A. H. Taft, Charleston; *secretary and treasurer,* Dr. Ralph E. Hughes, Laurens, S. C.

Ask Aid for Hospital Music.—The Hospital Musical Association of New York City, which for the past nine years has been providing musical entertainment for the sick and crippled in hospital wards throughout the city, is greatly in need of funds, owing to the fact that war charities had deprived them of the usual contributions. At the recent annual meeting Henry W. Goddard was elected president of the association.

Charitable Bequests.—By the will of the late Mrs. Fanny M. Thorpe of Philadelphia bequests are made as follows: To the Philadelphia Home for Incurables $10,000, also $5,000 after the death of another beneficiary, and in addition one-half of the residuary estates; to the Hahnemann Hospital $5,000; as well as one-half of the residuary estate.

By the will of the late Mrs. Louisa Horwitz Bullitt of Philadelphia a bequest of $3,000 is made to the Children's Medical Ward of the University of Pennsylvania Hospital for the endowment of a free bed.

By the will of the late Walter M. Steppacher of New York, and formerly of Philadelphia, the sum of $1,000 is bequeathed to the Jewish Hospital of Philadelphia.

By the will of the late Justus T. Brunner of Philadelphia, the sum of $24,000 is to be equally divided among the following institutions following the death of nieces and nephews: Philadelphia Home for Incurables, Children's Hospital, Midnight Mission, Pennsylvania Training School for Feeble-minded Children, Friend's Home for Children.

By the will of the late Gustavus B. Benson, Jr., of Philadelphia, the sum of $2,000 is bequeathed to Howard Hospital.

Death of Ivar Bang.—The *Hospitalstidende* for December 25 publishes the obituary of this distinguished scientist which occurred on the 11th of that month. He was the son of an eminent clergyman and born in 1869. He began his work in physiological chemistry after his graduation in medicine, about 1895, studying in his native land and also in Germany, finishing in Sweden with two years under Hammarsten at Upsala. His first professorship was in the University of Lund, in 1902. Here he remained till his death. After much miscellaneous research he settled down about 1910 to the study of the chemistry of the blood in which department he made his greatest reputation. He investigated especially the lipoids, blood sugar, and blood proteins, his so-called micro-methods of investigation adding greatly to his fame. For a man of his relatively short life to have accomplished so much means of course that he was a ceaseless worker. However, he was also a musician and an excellent 'cello player and took extensive summer pedestrian trips through Norway. His death took place at Lund and the cause, recognizable during life, was sclerosis of the coronary arteries and degeneration of the myocardium.

Obituary Notes.—Dr. MERCY N. BAKER, a graduate of the Woman's Medical College of the New York Infirmary, class of 1872, died in New York, October 12, 1918, of malignant disease. Dr. Baker was born near Bangor, Maine, November 11, 1840. She served in the infirmary as interne, later as attending physician from 1875 to 1884. She lectured on materia medica in her alma mater from 1874 to

1884. She practised her profession for more than 40 years. Beloved by her patients for her skill and her fine womanly qualities, she was a fine example of the family doctor.

Dr. HERMAN VEDDER MYNDERSE, a graduate of the Albany Medical College, in 1887, died at his home in Schenectady, on March 5, aged 58 years.

Dr. HAROUTYOUN TIRYKIAN, of New York, author, linguist, and for nine years physician to the Shah of Persia, died at the Manhattan Sanitarium, following an operation, on March 2, aged 74 years. He was a graduate of the University of Paris, in 1874, played an important rôle in the movement for the nationalization of Armenia, and was at one time president of the Armenian Political Chamber of Constantinople. He received the title Khan and was also decorated for his services to the Shah.

Dr. HARRY HIBBERD WEIST of New York, a graduate of Bellevue Hospital Medical College, in 1891, died suddenly at his home on March 6, aged 51. Dr. Weist formerly resided in Richmond, Ind., was a physician for the Pennsylvania Railroad and physician for the Exchange National Bank.

Dr. WALTER M. GOODALE of Saco, Me., a graduate of the Harvard Medical School, in February, 1919, an ex-Harvard Varsity oarsman, died of pneumonia following influenza in Cambridge, Mass., on February 21.

Dr. JOHN WAITE MITCHELL of Providence, R. I., died of pneumonia in that city on February 27, aged 70 years. He was graduated from Bellevue Hospital Medical College, in 1871. He was visiting surgeon at the Rhode Island Hospital from 1875 to 1903, consulting surgeon to the Catholic Orphan Asylum, St. Joseph's Hospital, and St. Elizabeth's Home. He was a member of the American Medical Association, the Social Science Association, and many other medical and lay organizations.

Dr. NATHANIEL L. EDWARDS, a graduate of the Leonard Medical College, Raleigh, N. C., died of spinal meningitis at his home in Bluefield, W. Va., on February 24, aged 49 years.

Dr. C. E. FARRISH of Mobile, Ala., while crossing the railroad near his home in his automobile, was struck by a freight train and instantly killed on February 21.

Dr. BROMWELL ARTEMUS ANDREW, a graduate of Bellevue Hospital Medical College, in 1869, died suddenly in his office in Jersey City, N. J., on February 28. He was for many years surgeon of the Jersey City Police Department.

Correspondence.

AD VOCEM "MUSK."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Walter C. Allen, M.D., takes the trouble of telling you in your issue of March 1 of a drug which is quite dead in his opinion. Still, Trousseau, Allbutt, and others, for instance my friends and pupils Elsner and Forchheimer, are called up by him to prove that musk is not so dead after all. Give me, if you please, a few lines to prove that the drug is not altogether extinct or useless. I have used musk a great many times and taught its use since 1860. Hundreds of my pupils have known of it, and many remember my writing about it.

In "A Treatise on Diphtheria," 1880, p. 157, I wrote: "A three-year-old child can comfortably take thirty to one hundred and fifty grams of cognac . . . or a *gram of musk* or camphor in twenty-four hours."

In my first edition of "Therapeutics of Infancy and Childhood," 1896, p. 338 (reprinted in my "Jacobi Colectanea," Vo. II, 1909, p. 59) you find the following: "The most powerful of all internal stimulants—Siberian musk—should be given frequently, viz., every half to one or two hours, in doses of from one-half to two grains, until from six to fifteen grains have been taken in the course of half a day."

The following quotations are taken from the third edition of "Therapeutics of Infancy and Childhood," 1903:

Umbilical hemorrhage, p. 103: "Feeding and stimulants (whisky, musk, ether, camphor)."

Typhoid fever, p. 191: "Of musk as a powerful stimulant I have seen the best possible results."

Asiatic cholera, p. 198: "Alcohol, coffee, caffeine, strychnine, camphor, tincture of musk are counted among the stimulants."

Scarlatina, p. 213: "When . . . high rectal temperatures and cold extremities, a mottled skin, and a cyanotic hue, the large amount of the toxin which has invaded the system demands strong stimulants —ammonia, musk, and camphor. They are better than alcohol."

Measles, p. 219: "Cardiac stimulants are required such as digitalis, spartein, camphor, and musk."

Diphtheria, p. 234, 235: Musk is mentioned as the best stimulant in very urgent cases of collapse.

Heart and bloodvessels, p. 454: "The centers of the medulla and of the spinal cord are influenced by strychnine and ergot; the vasomotor centers and centers of the heart by caffeine, camphor, ammonia, and musk."

Heart failure, p. 458: "Musk internally, strychnine subcutaneously, may be required."

In the artice on "Diphtheria, Its Symptomatology and Treatment," published in "The Twentieth Century Practice of Medicine" (reprinted in Collectanea Jacobi," 1909, Vol. I, p. 197), occurs the following: "The very best internal stimulant in urgent cases is Siberian musk. I prefer to give it from a bottle, in which it is simply shaken up with a thin mucilage. In urgent cases it ought to be administered in sufficient doses and at short intervals. When ten or fifteen grains given to a child one or two years old within three or four hours will not restore the heart's action to a more satisfactory standard, the prognosis is very bad."

In "Treatment of Influenza in Children," *Medical News*, December 15, 1900 (reprinted in Collectanea Jacobi, Vol. I, p. 354, 1909), I stated: "One of the best stimulants, useful in the gravest of all cases which are attended with collapse and heart failure, is sadly overlooked among us, viz., Siberian musk. I know of nothing better in the most urgent of cases. A child of two years should take of the 10 per cent. tincture five to ten minims every half hour until half a dozen or a dozen doses have been taken. Musk, together with large, hot enemata, has led me over many a difficult pass, and I again offer this experience of mine, which now extends over fifty

years, as a contribution to your aid in dire distress, always, however, reminding you of the fact that all these measures are not exclusive to influenza, but to all conditions of nerve exhaustion, no matter from what cause."

These are only specimens which I am sure will interest Dr. Allen.

A. Jacobi, M.D.

19 East Forty-seventh Street, New York.

THE SPAS OF AMERICA.

To the Editor of the Medical Record:

Sir:—In the issue of the 7th inst. an excellent article calls attention to the therapeutic value of the spas of America. My interest in this subject dates back many years. In the *Medical News* of July 10, 1897, I expressed the same views as follows: "A careful study of the American spas convinces me that we have in this country some of the highest types of these springs. A fertile field is open to the medical profession of this country which, if properly tilled, not only would bear good fruit to numberless invalids, real and imaginary, but satisfactory results to many colleagues who now labor in crowded towns and cities during the hot summer months."

How this was to be done was partly demonstrated by my description of thirty-three resorts which I had personally visited. It appears that your contributor still finds it necessary to make the same comment. He gives as one of the unfortunate reasons of failure that they have not been scientifically developed, and he properly concludes: "If the physicians of America would give greater cooperation and encouragement to the development of the American spas, founded upon an ethical basis, success would be insured." He does not tell your readers how to achieve this consummation; in fact, he indulges in the type of "scientific development" that is common among American spa doctors, by offering in two pages a complete epitome of hydrotherapy, without giving us a particle of scientific information about the beautiful resort in which he lives. Perhaps this omission is attributable to modesty. But how are your readers to learn anything ethical or scientific about the latter if he refrains from the former?

If we compare the literature furnished by physicians at our American spas with that offered by those in European spas, the reason for our failure will become evident. The latter do furnish scientific studies and practical contributions. And let me tell your readers how they obtain it. Nearly every spa physician in Europe visits the large clinics during the intervals between the seasons. I have known some to come to our shores. They not only endeavor to improve their knowledge of diagnosis and pathology, etc., but, with an eye to the main chance, become acquainted with the physicians of the cities by attending medical society meetings, reading papers before them, and other "ethical" activities. How many American spa doctors give like cooperation and encouragement to their spas? Here is "the nigger in the woodpile."

The physician who sends a patient to "the springs" is more concerned about the *mental equipment* of the doctor at the springs than with the *chemical composition* of the waters. Nauheim and Marienbad have illustrated that the scientific standing of the physicians at a health resort is the chief asset in its prosperity.

Simon Baruch, M.D.

51 West Seventieth Street.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, February 13, 1919.

Social Evenings at the Royal Society of Medicine.—Out of the war there has certainly emerged in London a spirit of goodfellowship in the medical profession which formerly did not exist. Many expressions of this can be seen in the institution of post-graduate classes to which medical men of all those nations which fought on the Entente side are welcome; facilities in the same way are extended for the visit of museums, institutions, and libraries, while the Royal Society of Medicine has now for over two years been a center of international goodwill and hospitality. The departure has been made by the Society now in holding weekly "Social Evenings" whose informal character is a clear derivative of military camaraderie. Every Wednesday evening a distinguished man is invited to deliver a discourse on some subject congenial to himself and of wide interest. After the discourse the library of the Society is available for informal discussion, at which it is certain that many professional acquaintanceships will be turned into personal friendships. The first discourse was given by Sir John Bland-Sutton on Gizzards, and the second by Sir Arbuthnot Lane on Intestinal Stasis. Other discourses are announced from Dr. Norman Moore, the president of the Royal College of Physicians of London, who will talk on English Morbid Anatomists, and from Sir William Osler, who will introduce to the audience the ever-fascinating character of Sir Thomas Browne. Dr. Henry Head and Mr. W. G. Spencer, whose addresses are entitled respectively "Disease and Diagnosis" and "Larrey and War Surgery," are certain of interested audiences.

Sir William Osler has for a long time made a steady cult of Sir Thomas Browne, while Dr. Norman Moore is famous as a medical historian and contributed many of the more important medical biographies to the National Dictionary of Biography. Mr. Spencer will introduce his hearers, in Larrey, to a man whom the great Napoleon described as the most valuable individual in his armies. Larrey was with the French armies in Italy, when he established in that country several schools of surgery; he was in the Egyptian expedition, and distinguished himself by his self-sacrificing attentions to the wounded; he served in the Australian campaigns, in Poland, in Spain, and in Russia; and finally he was wounded and taken prisoner at the Battle of Waterloo. Baron Dominique Larrey was a learned surgeon for his time, was one of the earliest organizers of an ambulance service, the author of the admirable Memoirs de Chirurgie Militaire and was an extraordinarily brave and patriotic man.

Medical Scholarship in London.—Seventeen

medical entrance scholarships and exhibitions, of an aggregate total value of about £1,550 will be offered for competition this year in connection with certain metropolitan medical schools. The scholarships and exhibitions are tenable in the faculties of medicine at Kings College, London, University College London, and at the medical schools connected with these two colleges, with the London Hospital, and with the Royal Free Hospital, this last school being the London school of Medicine for Women. That such valuable prizes are a stimulus to student work is undoubted, but what is really required in London is more pecuniary support for the teachers of these subsidized lads.

Pay in the Indian Medical Service.—The Secretary of State for India, Mr. S. Montague, has received a deputation from the British Medical Association regarding the pay in the Indian Medical Service to whom it was stated that the conditions both in pay and prospects of the officer in question would be at once bettered. Regarding the pay of the Service, the Secretary of State announced that an increase of pay amounting to 33 1/3 per cent. of present rates would be sanctioned. The object of this measure being to attract to the Service European candidates with the highest professional qualifications, the question whether Indian candidates entering the permanent Service after December 1, 1918, shall be eligible for increased rates of pay, and if so, to what extent and under what conditions, has been reserved for future consideration. All Indian officers already in the permanent Service on December 1, 1918, will be eligible for the increased rates of pay. As regards private practice Mr. Montague explained that, subject to the reservation that it must be under the control of Government, he was of opinion that it was to the public interest that the Service should enjoy as fully as possible opportunities of private practice, and he assured the deputation that no further restriction of the facilities for private practice now enjoyed by the Service was contemplated. The increasingly liberal attitude toward the natives of India is of good omen.

New Public Health Regulations for the Control of Epidemic Disease.—The toll exacted from the population by various forms of epidemic disease during the years of the war has been very heavy and has led the local Government Board to exhibit much activity. The secretary of the board has circulated to sanitary authorities and medical practitioners a general order containing the Public Health (pneumonia, malaria, dysentery, etc.) Regulations for 1919 and a circular explaining these regulations. Their object is to secure better control over certain epidemic diseases prevalent or threatened at the present time and to increase the facilities for their treatment. The regulations impose the duty of notification by practitioners of any cases of pneumonia occurring under their care, if primary or the result of influenza. All cases of malaria, dysentery, and trench fever must be notified unless the practitioner knows that this has been done in the same district within six months. The regulations in regard to the handling of food by carriers are extended to the enteric fevers, and the duties in relation to lice-borne disease to typhus and relapsing fever. Local authorities may provide medical assistance for any of the diseases named in the regulations. The order it will be seen is remarkably far-reaching, while asking for powers of diagnosis from the general practitioner which it is a high compliment to credit him with. But many thousands of general practitioners during the past four and a half years have seen malaria, dysentery, and trench fever in huge quantities, so that the discrimination necessary to the discharge of the order will be forthcoming.

The Curability of Cancer of the Larynx.—At the last meeting of the Medical Society of London, Sir St. Clair Thomson, the well-known laryngologist and surgeon to the throat department of King's College Hospital, read a paper upon intrinsic cancer of the larynx in which he showed the remarkable progress that has taken place in the operative treatment of what 33 years ago was considered a necessarily fatal condition. Laryngofissure which now gives the sufferer a reasonable hope of recovery from intrinsic cancer, was unsuccessful in the great Billroth's hands, and was condemned by Morell Mackenzie, Henry Butlin, an original and bold operator, and Felix Semon, as an unreliable procedure. How far this is changed is seen from Sir St. Clair Thomson's figures. Of 38 cases of laryngeal cancer on which he has operated, 22 were alive at subsequent periods of from 6 months to 10 years without manifesting any symptoms of return. Moreover, none of the 38—a total made up of 34 males and 4 females—died from any cause directly attributable to the operation. In successful cases the resulting voice was, said Sir St. Clair Thomson, usually a good one. It has been his custom to keep the patient silent after the operation for at least 3 weeks, and then to permit whispering. After which special reeducation might be required, but as a rule it was not necessary, while school-masters and clergymen have been found able to carry on their callings. He now made whispering compulsory for 3 weeks only.

The Medical Parliamentary Committee.—This committee, which has the laudable if extravagant pretext of making itself, by democratic election, a truly representative committee of the medical profession, gave a dinner this week to the new medical members of parliament, asking the heads of many great departments in medicine to meet the new senators. The chair was taken by Sir Watson Cheyne and the principal guest was Dr. Christopher Addison, formerly demonstrator of anatomy at St. Bartholomew's Hospital and now president of the local Government Board. Dr. Addison in a long and carefully rendered speech promised that in connection with the Ministry of Health Bill, which was going to be read in parliament immediately, he would institute Professional Consultative Councils to whose views he would listen and from whom he would expect a great deal of strenuous assistance. But he allowed that there was no organization in the profession that really represented collective medical views, and this is

exactly what the Medical Parliamentary Committee desires to do. At the dinner a forceful plea for medical unanimity at an important juncture of history was advanced by Mr. E. B. Turner, formerly chairman of the Representative Body of the British Medical Association; and if that body should be found meeting with the Medical Parliamentary Committee a federated committee of advice would, *ipso facto*, be formed. Mr. Turner, a well-known London general practitioner, who enjoys the rather unusual distinction for a general practitioner of the F.R.C.S., Eng., was in his youth a famous foot-baller, and he drew his many examples of the value of cooperation, and unselfish team-work from his recollection of the tactics employed in conducting a football fifteen to success.

American Gifts to Portsmouth.—Much valuable hospital stores and comforts supplied by the American Red Cross to the U. S. Base Hospital at Portsmouth, has been given to the Mayor of Portsmouth for distribution among the charities of his city. All the constructional work necessary to turn the Portsmouth Asylum into a hospital has been presented free to the asylum, in addition to the payment made for dilapidation. Portsmouth appreciates such visitors as these.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, February 15, 1919.

Meeting of the Academy.—The President of the Academy of Medicine of Buenos Aires telegraphed to the Paris Academy the admiration of himself and colleagues for the self-sacrificing devotion displayed by the French Medical Corps in the war, and their congratulations for the splendid victory of the Allies. Dr. Simon Flexner of New York was received as an honored guest by the Academy and warmly applauded upon his entrance.

Dr. Leguen presented an interesting paper upon the vesical retention which often accompanies an hypertrophied prostate, claiming that, contrary to the generally accepted theory that the cause lies in the mechanical closing of the vesical opening by the enlarged gland, often the cause is found in an hypertrophy of the neck of the bladder, causing it to lose its elasticity and ability to open; this is the reason, he claims, why the removal of the prostate does not at times give the results expected.

An American Memorial.—Mr. Wanamaker of Philadelphia recently made public the suggestion that America build in Paris a monument to the Allied dead in the cause of the right, and much discussion has followed—a proposal made by Dr. P. K. Brown to build a research laboratory appeals to one as a splendid idea.

We Americans want to leave behind us something that will be a live and lasting memorial, something built on what we have developed in common in our work for the right of our fellow men to live and enjoy to the full the blessing of freedom and fraternity, something that will grow in influence, binding us closer and closer to the French people and our other Allies, giving us something to come back to for our own good and a common meeting ground in an intellectual sense. If the memorial could take the form of an Inter-Allied Hospital and Research Laboratory it would serve all these purposes and more.

Thousands of young French women from the best homes have given gladly four years of hospital work to the Service de Santé. They volunteered to meet a demand for nursing that France could not supply. French training schools have not attracted the class of women that our best American schools have, nor have those who have entered French schools had what we would call a nurse's training. It will be impossible for many of these young women to go back to the social lives they led before the war. Some organized expression of their feelings they will surely find, and what can they contribute to France more needed than to give her a system of trained nurses of the highest type, the product of their desire to memorialize in a constructive social form the work they did for their country in the hour of her need? A school that would fill the requirements of these women could be a part of the Memorial Hospital.

There is little need to dwell upon the benefits through science to humanity at large that would come through provision for a common meeting ground of English, French, Italian and American research workers in medicine. The war has shown that centering men on the problems in hand resulted in rapid advances along many lines. Most of the unsolved problems will be abandoned now for months with the rapid demobilization bound to go on. Problems like cancer, pneumonia, etc., are being worked on all over the world, but the advances would be far more rapid if the important agencies would be kept closer in touch through a central organization to which could come all delegated workers. We Americans want to come back to France, we want to feel that we have a common forum where we can meet our Allies for consideration of our common problems. The whole subject of exchange professorships needs to be handled on a new and broader basis and made a rule, not an incident. How better can we do it all than by building a memorial that will always stand for the cause of humanity for which we have fought successfully?

War Neuroses.—Recently there appeared an article from an American base hospital which gives an entirely incorrect account of the outcome of cases of war neuroses. The article conveyed the idea that no one recovered sufficiently to perform military service, when, as a matter of fact, practically all recover.

After a nearby shell explosion, a short period of trembling is not unusual. This may last only a few minutes or a part of a day, and ordinarily these patients are returned to duty by the battalion and regimental medical officers. When the stage of absolute exhaustion is reached, nervous symptoms are likely to develop. These cases usually reach the triage, from which place a large percentage return to duty. Forward neurological stations receive and return to duty many of the cases that have been evacuated from the more forward areas, and this hospital receives only those severe cases passed on by three other medical posts, cases which are not expected to recover speedily.

With these cases the hospital returns to duty the following percentage:

Class A	19 per cent.
Class B	44 per cent.
Class C	32 per cent.
Class D	5 per cent.

Thus 19 per cent. are ready for immediate combat duty, an additional 44 per cent. presumably will be ready after a short interval, making a return to the line of 63 per cent., with 32 per cent. more, 95 per cent. in all, capable of rendering A.E.F. service. Only 5 per cent return to the United States, and even they are not incurable, return indicating in this instance a duration too long to warrant continued care in France

A war neurosis which persists is not a creditable disease to have, as it indicates in practically every case a lack of the soldierly qualities which have distinguished the Allied armies, and it will not be a serious problem. The population of the United States will easily absorb the few scores of unrecovered cases that will exist after the expiration of six months of peace, and no one should be permitted to glorify himself as a case of "shell shock." It should become widely known that a persistent war neurosis is not something of which to be proud. It is not the same as an honorable wound. A temporary state of a few days' duration from which a person quickly recovers is not discreditable, but if the symptoms persist after rest and treatment then it is a disorder of the will, and one does not boast of a weak will. In an army of perfect men there would be no "shell shock" problem.

University Union in Belgium.—Mr. Harmignies, the new Minister of Science, Literature and Public Education, has just been approached with a suggestion for the foundation in Brussels and one or two other large Belgian cities of homes for American university students, such as the one created in Paris during the war, under the title of the American University Union in Europe, to meet the needs of American university and college men and their friends. It is expected that many militarized American university men will settle in France and Belgium, and that many younger Americans will come to study in universities of both these countries in order to perfect their knowledge of the French language and of European matters. For this reason, the creation (in Brussels, to begin with) of an American Students' Home is being mooted.

Mr. Harmignies has hailed the idea with delight as a means of encouraging Belgian intercourse with the United States. Measures therefore will be taken by the Minister, in conjunction with the Paris Committee of the American University Union in Europe, to realize the scheme as soon as quicker communications have been established between Brussels and Paris and when things have taken on a more normal aspect than at present.

Evacuation of Red Cross Hospitals in Paris.—The American Red Cross military hospitals of Paris are being evacuated according to arrangements made to close them as soon as possible. Hospital No. 1, at Neuilly, will probably be the first to close. This hospital has occupied the building that was intended for the school at Neuilly, the Lycée Pasteur, since August, 1914, and the municipality of Neuilly is now anxious to open the school in January. The hospital is now caring for about 600 patients, who are being sent to convalescent homes as rapidly as possible. A few months ago the number of patients was 2,000.

Hospital No. 5, at Auteuil, is also being quickly emptied and will probably close about the same time as the Neuilly hospital.

146, Avenue des Champs Élysées.

CANADIAN LETTER.

(From an Occasional Correspondent.)

Montreal, March 1, 1919.

Conference of Public Health Officers at Ottawa.—On February 3, 1919, representatives of a number of the Canadian provinces met in Ottawa at the behest of Sir Thomas White, acting premier, to discuss the venereal problem and legislation for the control of the same. Each province sent its chief health officer. Among those present were Major General J. T. Fotheringham, D. G. M. S., Dr. P. H. Bryce, chief medical officer Department of Immigration, Ottawa; Capt. Gordon Bates, Toronto; Lieut. Col. I. W. S. McCullough, C. A .M. C., chief officer of health, Ontario, and Dr. Elzear Pelletier, Superior Board of Health, Quebec.

The following resolutions were passed:

"Whereas, in the reconstruction of Canada, following the great war, there are very many important problems that must be taken into consideration, such as finance, soldiers' reestablishment, labor, etc. Among these the conservation of the health and lives of the people is equally, if not most, important to be dealt with, as life is the country's greatest asset. Therefore, be it

"Resolved, That this conference whose personnel is made up of representatives from the various provincial governments of Canada, together with the chief medical officers assembled at Ottawa, for consideration of the venereal disease question, memorialize the Government of Canada that it is in the interests of the future health and life of the citizenship of Canada that there should be immediately established a Federal Department of Health.

"That the representatives of the several governments and health departments of the provinces of Saskatchewan, Manitoba, Ontario, Quebec, and New Brunswick, assembled in conference, are agreed, subject to the consideration of the governments of the respective provinces, that the following general principles are necessary in any provincial legislation looking to the prevention and control of venereal diseases in the said provinces: (1) Compulsory notification; (2) compulsory treatment; (3) standardized treatment; (4) authority to examine persons suspected of being affected with venereal disease; (5) prevention of quack treatment, quack remedies, and of advertising of such treatment and remedies; (6) right of entry of public health authorities; (7) prevention of infection; (8) power to make regulations by order in Council; (9) liability of municipalities or local authorities; (10) penalties.

"That the criminal code of Canada be amended so that a person who is suffering from venereal disease in a communicable form, who knowingly or by culpable negligence communicates such disease to any person, shall be guilty of a criminal offense; provided that (1) a person shall not be convicted under the section if that person proves

that he or she had reasonable grounds to believe that he or she was free from venereal disease in a communicable form at the time the alleged offense was committed; and (2) no person shall be convicted of any offense under this section upon the evidence of one witness, unless such witness be corroborated in some material particular by evidence implicating the accused.

"In view of the fact that the Government of Great Britain supports the treatment of venereal disease in the proportion of 75 per cent. to that of 25 per cent. paid by the local authorities, this conference respectfully urges upon the Government of Canada to provide financial assistance to the provinces on a scale similar to that in Great Britain, for the treatment of these affections.

"That the conference suggests that all seamen coming within the purview of the immigration act be examined for freedom from venereal disease before being allowed ashore at Canadian seaports.

"Whereas, successful control of venereal disease depends, among other factors, for the free or readily available and adequate treatment of these diseases, and whereas the cost of one of the remedies for the cure of syphilis, viz., salvarsan, and of other remedies of that character, is excessive; and whereas the production of the remedy in Canada is monopolized by two persons or firms who have been licensed to carry on such production, therefore, be it

"Resolved that this conference do respectfully recommend that the Government of Canada shall give the right of the production of salvarsan and other remedies of this nature to any person or firm or corporation satisfying the head of the health department of any province; or in the event of the establishment of a federal department of health, of the head of that department, of his or their ability to successfully produce a satisfactory product of the kind."

The conference further recommended that another meeting representative of social agencies should be called to discuss the constructive social measures which may be undertaken to combat the existence of venereal disease in the Dominion; and also that legislation be undertaken to prevent the advertising, selling, or giving of quack medicine to cure venereal disease.

Report of the Committee of Sixteen of Montreal.—Another report of the Montreal Committee of Sixteen, formed with the object of investigating vice conditions in Montreal, making these public, and suggesting plans for improving the existing state of affairs, was issued on February 22. This report emphatically recommended the policy of repression. It is stated that experience gathered in all parts of the world has shown that absolute repression is the only practical method. Toleration is not only ineffective, but contrary to Canadian law. The Committee of Sixteen includes a program on venereal disease and a campaign against it as part of its work, because a strong propaganda of education in regard to the peril will strike at the very roots of commercialized vice.

Feeble Mindedness in Canada.—The question of feeblemindedness is important everywhere. It is a prominent factor in the production and dissemination of venereal diseases, as perhaps the large majority of women who lend themselves to immorality are of a low mental grade. This being so, it is of the first moment, in the interests of public health, to deal with the feebleminded in such a way that they will not be a menace to the general population. In Canada the problem of the feebleminded is greatly exercising the minds of social and medical authorities. Immigration lets into the country a large number of those who, regarded from the outlook of mentality, are weak when not really degenerates. A commmission has been sitting recently in Ontario, before Mr. Justice Hodgins, to inquire into the whole matter and to devise, if possible, means to remedy the situation. Dr. C. P. Johns, physician at the jail farm, Toronto, testifying before the commission a few weeks ago, suggested that there should be established a clearing house in Toronto for mental defectives, where experts could examine patients and decide as to the institutions in which they should be placed. He advocated sending them to farm colonies, but not too many to one place. Dr. Johns said that from 35 to 40 per cent. of 280 inmates at the jail farm were subnormal. Another witness was Canon Tucker of London, who said that he thought there were between 10,000 and 50,000 feebleminded persons in Canada. Dr. Lilian Langstaff, superintendent of the Women's Industrial Farm, Toronto, said that 40 per cent. of the inmates there were mentally defective. She suggested classification as a solution, as moral degenerates taught vice to the ordinary feebleminded person.

Annual Meeting of the Montreal General Hospital.—The annual meeting of the General Hospital, Montreal, was held on February 18, when it was pointed out that more state and municipal support was necessary to enable this large but meagerly endowed hospital to continue its work on the usual scale. It was argued that the burden of caring for the sick who are unable to pay for hospital treatment should be taken over by city and province. In Toronto the hospitals are financed by the city to the extent of $1,000,000. Toronto pays $1.25 per day to each of the general hospitals for maintenance of each indigent patient, and for each such patient the hospitals received 32 cents a day in a year from the Province of Ontario. Montreal grants totaled only $5,000, and grants to the same amount in the year came from the Province of Quebec. The secretary's report showed that 7,295 new patients had been received during the year. Of these there were 2,035 public cases, 1,206 soldiers, 355 sailors, 1,038 private cases, 631 semi-private. Maximum number of patients in the hospital at any time was 441; minimum, 291.

Personal.—Lieut.-Colonel T. A. Starkey, Montreal, has been appointed consultant in sanitation in Military Districts 4, 5, 6, and 7.

Major Brefney R. O'Reilly, M. R. C. S., of Toronto, has been gazetted an officer of the Order of the British Empire.

Dr. Richard Andrews Reeve of Kingston passed away with dramatic suddenness on the night of January 27. Dr. Reeve was returning from a committee meeting of the Academy of Medicine, Toronto, when he fell dead on the street. He was one of the best-known eye specialists in Canada. He was born in Toronto in 1842, and was graduated

from Queen's College, Kingston, in 1865. Shortly afterward he commenced practice in Toronto, and was assistant surgeon of the Toronto Eye and Ear Infirmary, 1867-72. He was also oculist and aurist to the Toronto General Hospital, lecturer on ophthalmology and otology in the Toronto School of Medicine, and became a professor in the University of Toronto in 1887. Dr. Reeve received the honorary degree of LL.D. from Toronto in 1902, and from McGill and Birmingham universities in 1911. He was dean of the medical faculty of Toronto University from 1896 to 1908, and president of the Alumni Associates from 1904 to 1907. He was president of the British Medical Association at its meeting in Toronto, in 1906, and was also president of many Canadian medical associations.

While the late Dr. Reeve shone in his profession, and attained the highest eminence, it is as a man, even more than as a learned and skillful exponent of his chosen specialty, that he will live in the memories of all who knew him. He was of such transparent honesty and nobility of character that the possession of these attributes was obvious to those who knew him only slightly. He was so modest and unassuming that he carried his wide scientific knowledge with a total lack of arrogance. He was imbued with the conviction that it is the wise man who knows how little he knows. In his daily life and in his intercourse with his fellow men he was ever courteous and considerate. These were innate qualities which marked him from the ordinary run of individuals.

2. Chronic Headaches with Painful Points.—George T. Stevens calls attention to the common form of frequently recurring headaches associated with painful points in the region of the back of the head and of the neck and back. Such pains have often been attributed to rheumatism, or to the general nervous disturbance caused by the headache. They may be felt at the location of the occipital protuberances, at the extremity of the spinous process of the seventh cervical vertebra, at the lower points of the scapula, at the vicinity of the twelfth dorsal vertebra, this point being more or less diffuse, at the turn of the shoulders, also diffuse, or at the point at the lower extremity of the spinal column. There may also be frontal, diffuse pain, or pain at the vertex of the skull. Some of these points are painful even when headaches are rare. Such pains were formerly attributed by the author to the principle of reflex, particularly from eye peculiarities, and it was found that with the correction of certain eye defects the pains as well as the headaches often disappeared. Examinations by the tropometer and the clinoscope, however, showed that the view of reflex was too narrow and that many phenomena hitherto considered to be of a reflex character were due to specific mechanical causes. The author became convinced that these pains are associated with the muscles whose attachments at the points involved are subject to special tension under certain conditions and that they are due to a lack of proper equilibrium, the position of greatest equilibrium being the most restful. The next step was to determine the cause of the loss of equilibrium between the head and the body, which affected the splenius capitus and produced pain at its attachment (the most common of the painful points). This cause he believes to lie in the natural desire for clear vision which is dependent upon certain adjustments of the eyes. For instance, if the plane of vision is somewhat depressed, as it is in case the orbits are adjusted in such a way as to induce such a depression of the plane of vision, then both the muscles immediately affecting the direction of the eyes and the surrounding muscles of the ball are brought into action. Furthermore, the muscles at the posterior aspect of the cranium are enlisted in the work of adjusting the plane of vision to its most effective level. The position of the head is also influenced in order to adjust for certain declinations. On the other hand, if the plane of vision is too high, which it may be by reason of the direction of the orbits to the cranium, or if, by reason of certain forms of declination of the vertical meridians, an approximation to the best adjustments of these meridians can be made by throwing the head forward, this is accomplished by means of adjusting the muscles of the neck. These facts have been often stated, but are too generally overlooked. The headaches themselves are the response to similar influences to those which give rise to the painful points, but on account of the more general and, in many cases, more flexible attachments of muscles involved, the pain is more diffuse. Other general symptoms are associated with these pains, such as malaise, nausea, and vertigo. These may arise from the pressure of muscles on certain nerves or from the position of the cranium in its relation to the body. Fatigue, impure air, malnutrition, etc., may be contributing causes. The remedy, however, lies in attention to the condition of the eyes. The use of properly adjusted glasses will serve as effective and permanent means of relief in a certain proportion of cases; in others the position of the eyes in relation to the cranium may require adjustment. The question of the sufficient rotations of the eyes and the great importance of declination should be realized and made the subject of careful treatment.

5. The Transmission of Infection Through the Eye.—Kenneth F. Maxcy draws attention to the following facts: (1) That the eyes offer a relatively large surface area for the reception of droplets sprayed from the mouths of other persons. (2) That an organism introduced into the conjunctival sac may be recovered from the nose in five minutes, from the throat in fifteen minutes, and from the stool in twenty-four hours. (3) That the upper respiratory tract of a person wearing a properly constructed mask may be infected by exposing the eye briefly to direct droplet spray. (4) That this portal of entry is of importance in the transmission of acute respiratory infections. He also points out that the frequency with which respiratory infec-

tions, such as acute coryza, measles, and influenza, begin with a conjunctivis suggests that the entrance of the causative organism by way of the eye may not be uncommon. At all events, the evidence is sufficient to warrant serious consideration of this portal of entry in planning measures for the prevention of the spread of contagion. Moreover, the pathologist at the necropsy table should remember that infectious material splashed into the eyes is just as potent as if it had been directly implanted on the mucous membrane of the nasopharynx.

2. Medical Aspects of Aviation.—L. E. Stamm draws attention to the importance to the aviator of good muscular tone with the power of nice control and adjustment. Deficiency in this respect is characterized by the pilot instructor as "heavy on controls." Another factor of importance is "conscious control of the muscles," which means the power not only to control the movement of muscles but to relax them. The inability to relax or inhibit muscular contraction shows a lack of conscious control of the motor mechanism, and of complete *rapport* between the muscles and the brain nerve centers. It may be easily demonstrated by instructing the person to lie down on the floor and relax all muscles; in many cases upon gently raising a limb and then letting it go, instead of dropping limply, it remains in the air, showing that the muscles are rigid and not relaxed. In training for aviation a pupil may lose his head and because of this unconscious rigidity hang on to the joy stick, making it impossible for the instructor to take proper control. Stamm suggests that instruction in the proper control of the muscles should be embodied in the ordinary physical training. In the air circumstances arise continually which call for rapid decision, discrimination and judgment, and the proper exercise of these faculties often decides the fate of the aviator. Above all things, a good pilot requires a mental constitution that can take in all the circumstances of a situation and make a rapid and quick decision. He requires not only quick and accurate co-ordination between the senses and the muscles, but also between these and the higher mental functions. Testing for the "simple reaction time," therefore, is of little value in candidates for the air service; what one requires is to test the ability of the candidate to respond quickly and accurately under conditions in which the higher *conscious* mental functions are involved. In order to test this many forms of apparatus have been devised, but the difficulty has been to find one accurate and rapid and at the same time simple enough for practical use. The author has devised such an apparatus, which has proved of value. It consists of a chronoscope which registers to 1/100th second, and is worked electrically by a hammer from a coil and accumulators. There are four signals, two differently colored lights, an electric horn, and an electric bell. The operator has a switchboard, by which any one of the signals is put in the current, and the signal is given by touching the key. The candidate sits opposite the operator and places his right-hand first finger on the brass plate, which is equidistant from the three keys. The end keys are for the corresponding lights and the middle key is for the horn or bell. When the operator presses a key one of the signals is given and at the same time the chronoscope starts. The candidate responds by touching the appropriate key, which stops the chronoscope, and the reaction time is read off in 1/100th seconds. The candidate is first tested for the simple "automatic reaction time" by one signal, having been told beforehand which signal to expect. Though the author attaches no value to these simple tests, they enable the candidate to get used to the machine. Tests are then made with two lights, then with two lights and horn, and finally with all four signals, given haphazard. In the last test the candidate is told to keep his finger on the brass plate instead of using the key previously used for this signal. This involves mental inhibition. The author has tested 150 cases, including pupils and experienced pilots, and has found a remarkable correspondence between the results obtained and their capacities. He has also found that the results of the tests in pupils and the criticisms of their instructors have shown a marked correspondence. These tests involve considerable adjustment and co-ordination between the senses and the muscles and at the same time call for an accurate working of the higher mental functions and prolonged mental effort. The "will" factor is also brought into play; this may be negative, in which case the candidate will not do his best, or it may be very positive, when the candidate will exceed for a time his normal power of reaction, but, mental fatigue setting in, be unable to keep up the pace he has set for himself. The two good types are those in which the reaction times are very quick, but in the final tests several mistakes may be made, and those who are absolutely accurate but appreciably slower in reacting to signals. Another important characteristic in the aviator is emotional stability or "guts." The individual who is liable to serious emotional disturbance or, in the language of the service, liable to get the "wind up," is constitutionally unfitted for work in the air, since no matter how good his judgment may be, in the presence of danger it is inhibited by the emotional disturbance of fear. Stamm has found the pulse rate under ordinary medical examination a very fair guide to detect the "windy" type. He points out that the instability does not appear to be in the vital centers, but in the higher nerve centers controlling them. Then there is the typical facial expression—a furtive, apprehensive look. In cases where this is marked, the author states he would have no hesitation in throwing out its possessor as undesirable for the air service. On the other hand, though quick, accurate judgment and emotional stability or "confidence" are essential qualities, over-confidence in a judgment that does not justify such confidence probably leads to just as many crashes in the air as "wind up" or losing one's head. Aviation requires, above all things, a strong, tough nervous system, for which the author suggests the term "nerve physique," which is found in young men who have led an outdoor life. Stamm disagrees with those who believe that the fighting scout should possess the fighting spirit and be able "to see red." In his opinion, cool agressiveness with judgment unclouded by any emotional disturbance is what is required. Any excess of alcohol or tobacco would, of course, act adversely upon the nervous system, which must be kept up to pitch. Since horse riding is one of the best physical exercises and comes nearer controlling an aeroplane than any other ground occupation, the author suggests that every aerodrome should have its stables. What better place than an aerodrome for polo, he asks?

3. Some Simple Tests for Physical Efficiency.—Lieutenant-Colonel Martin Flack describes certain tests by which the physical efficiency of an individual may be computed. The technique is important, as it is essential that the tests should be carried out in the same way on all occasions. The first of these is the *response of the pulse to exercise.* The sitting rate of the pulse should be first taken, then the standing rate; if unsteady, the pulse should be counted in periods of five seconds until a steady rate is obtained. Standing before a chair, the candidate places one foot upon the seat of the chair and steadily raises his whole body to the height of the seat five times in fifteen seconds, one foot being retained on the chair throughout. The examiner should regulate the speed and rhythm by swinging his arm forward and backward, holding the candidate's wrist with his fingers on the pulse. The subject still standing, the examiner then counts the pulse rate in five second intervals and notes

the acceleration and the time taken to return to the previous rate. The increase should be about 20 and the time of return to normal 15-25 seconds; more than 30 seconds is suggestive of cardio-vascular inefficiency. *The breath-holding test* consists in getting the subject to hold his breath without any preliminery deep breaths. This should be done in the following way: A deep expiration followed by filling of the lungs, clipping the nose, and holding the breath as long as possible. The subject should merely be told to breathe out and breathe in as far as possible and then hold the breath. At the end of the test the subject should be asked as to the sensations experienced. A normal answer would be that the individual "had to give up," "felt he would burst." The author has found that people who are likely to suffer from "oxygen want" give up quickly and state that the "blood rushed to the head," "things became blurred," etc. A man without resolution, of course, will give up early. Colonel Flack points out that if a lungful of oxygen is taken instead of air the time of holding the breath will be increased from one and a half to two and a half times and that break down in the first case is due to oxygen want, because when one breaks down in holding the breath on oxygen the symptoms are quite different—headache, sweating, etc. Furthermore, the power to hold the breath is diminished at altitudes. An efficient man at altitudes is a deep breather, whereas the inefficient man is a panter. In the test performed on forty successful pilots the time of holding the breath averaged about 69 seconds, the vital capacity averaging 3,800 c.c. with a minimum of 3,400 c.c. In a number of men sent up for medical boarding, the time of breath-holding was not more than 45 seconds, usually much less. The third test is a combination of the two former tests—*the time the breath can be held after exercise*. In the unfit, the breath-holding power comes right down, probably by 30 seconds. In the ordinary breath-holding test the standard has been set at 45 seconds. The vital capacity can best be measured by a gas meter, preferably one made by an English firm, as this has the advantage over the German model that its capacity cannot be overshot. In testing officers who had broken down, a number were found to be under the minimum of 3,400 and in some the vital capacity was only 2,800 c.c. Captain Bazett has shown that in addition to the tests mentioned, if the respiration rate is multiplied by the ventilation per minute and divided by the vital capacity, a very good indication is obtained of the power of a pilot to fly. The tone of the abdominal wall may be measured by a U tube manometer filled with mercury, with movable scale. This instrument may also be employed for the sixth test, when the subject is asked to empty the lungs, fill up, blow the mercury to the height of 40 mm. and hold it there without breathing as long as possible. The nose should be clipped. The behavior of the pulse during this test should be noted, a large rise in rate—*e. g.*, from 72 to 132 or 144—is unsatisfactory. Such cardiomotor instability is frequently associated with flying stress and is indicative of the need of rest, the subject not being in a condition to be allowed to continue to fly. The tests described should be used in combination and would be of the greatest value in maintaining the efficiency of a flying station. Every pilot should be examined from time to time and only allowed to do special duty if found fit; in fact, this has been done at one station, with very satisfactory results. These tests would also be of value in measuring trench fatigue, industrial fatigue, and fatigue in women workers; also for the grading of people for positions of trust. With special standards set according to age, they might also be used in assessing the maintenance of physical efficiency in children.

1. A Note on Sodium Morrhuate in Tuberculosis.—Lieutenant-Colonel Sir Leonard Rogers has used a preparation of sodium salts of the unsaturated fatty acids of cod liver oil after extraction by ether in the treatment of tuberculosis. This preparation he has termed Sodium Morrhuate. It is obtained by a process similar to that by which sodium gynocardate is made from chaulmoogra oil, which has proved of great value in the treatment of leprosy. As both tuberculosis and leprosy are produced by an acid-fast bacillus, Rogers, in 1916, suggested the administration of this drug in the treatment of tuberculosis. As, however, in rare cases of leprosy prolonged febrile reactions with temporary exacerbation of the disease may follow sodium gynocardate given intravenously, he hesitated to use it in that way in phthisis. Some gain in weight followed its administration by mouth, but hypodermically it caused painful local indurations. Under these circumstances, the author was led to prepare sodium morrhuate, the subcutaneous infection of which has proved to be almost painless. A year's experience with this preparation in the treatment of leprosy has shown it to be of great value and it would appear, therefore, that the products of chaulmoogra oil possess no specific property in regard to that disease, a fact which lends support to the author's view that the sodium salts of the unsaturated fatty acids of the two oils act in some way on the coating of the acid-fast bacilli, that of tuberculosis having been shown to contain palmitic and other unsaturated fatty acids. In the treatment of tuberculosis a 3 per cent. solution of sodium morrhuate is sterilized in an autoclave and ½ per cent. carbolic acid added. This may be injected subcutaneously with very little pain, and also intravenously. The preparation has been used by the author and also by several other observers and full reports of their work will be published in the *Indian Journal of Medical Research*. In phthisis slight febrile reactions have followed the administration of sodium morrhuate, and occasionally there has been slight hemoptysis, indicating a local reaction in the affected lung tissue, which clearly points to a definite action of the tuberculous lesions. No harm has followed such reactions; frequently the temperature and other symptoms have improved decidedly after them. Their occurrence indicates the necessity of increasing the doses very gradually. The author usually begins with ½ c.c. of the 3 per cent. solution and increases by 2 to 4 minims at each injection, which may be given two or three times a week until reaction occurs; then after a week's interval the dose is reduced. Injections are given subcutaneously until they reach an inconvenient size, such as 2 c.c., when intravenous injections are commenced with ½ c.c. and gradually increased. One observer, Dr. E. Muir of the Kulna Mission Hospital, finds that he gets the gest results by pushing the dose until a febrile reaction occurs, and then returning to a small dose and gradually increasing it. In febrile cases the doses should be smaller and increased more slowly. Muir has gone up to 4 c.c. intravenously two or three times a week. This treatment has resulted in reduction and cessation of fever, diminution of expectoration and cough, and steady gain in weight. The tubercle bacilli decrease in numbers and may in time disappear; they commonly show deficient acid staining and a granular or beaded appearance, indicating that they are actually being destroyed within the tissues. As the author's opportunities for clinical trials have been limited, he submits abstracts from the reports of other observers. Muir considers the results, after a year's experience of the new treatment, to be far superior to those produced by tuberculin and "sufficiently encouraging to lead to the hope that the cases under treatment will be finally cured." As the climate at Kulna is extremely inimical to tubercle, spontaneous improvement can be eliminated; yet in all but the most

advanced cases improvement was obtained. In gland cases reactions in the form of fever and local swelling were noted, but were followed by marked improvement. Captain Knowles, director of the Pasteur Institute, Shillong, though not satisfied that the drug is a specific cure, believes it to be the best line of treatment for tuberculosis in general. Remarkably satisfactory results have been obtained in two cases by Major C. Brierly, I.M.S., civil surgeon of Peshawar. While duly recognizing the responsibility of bringing forward a new treatment for such a serious and widespead disease as tuberculosis, the author is convinced of the harmlessness of the doses recommended. He draws attention, however, to the necessity for caution in pushing the drug beyond the limits which have so far proved safe. With this caution he feels justified in bringing this remedy before the profession in order that further observations may be made and the indications and contra-indications for its use worked out.

The Famine in Germany.—This subject was discussed in an extraordinary meeting of the Berlin medical societies on December 18, 1918. The meeting took place with J. Orth, president, in the chair. The reports were read by M. Rubner, E. Kraus, A. Czerny, Hamel, A. Weber, L. Kuttner, Beninde, and Wurm, who claimed that the food situation was lamentable. Since 1916 the progressive reduction in the rations has been accompanied by an increase of disease—tuberculosis, pulmonary affections, amenorrhea and sterility, and mortality among infants. The speakers maintained that Germany was the innocent victim of its victors, and unanimously voted, as would naturally be expected, that steps be taken to ask the Allies rapidly and abundantly to furnish Germany with food. If this could not be done the sanitary and moral consequences would result in fearful catastrophe.

The Etiology and Epidemiology of the Grippe.—F. Neufeld and P. Papamarker state that in the absence of reliable documents of the etiology of influenza, steps should be taken in the way of social prophylaxis, namely, to instruct the public as to the danger of contagion from drops of expectoration.

The Etiology of the Grippe.—E. Leschke has at length obtained, after filtration of the pulmonary juices which are then placed for a certain time in an incubator, a growth on broth of corpuscles which were hardly visible in the microscope (magnified 1,500 diameters). The inhalation of this culture of filtered virus produced a febrile process, having the characters of influenza, in several persons. It is to be remarked that this process immediately followed the experimental infection without any incubation period.

Heredity in Relation to Ophthalmoscopy.—A. Vogt considers ocular malformations in relation to the laws of heredity. This article confirms in a general way the results of well-known general biological researches, viz., that malformations of the eye are hereditary, become combined, and skip over generations according to Mendel's principles. It goes without saying that heredity is also to be found in normal cases. The ignorance of these laws of heredity resulted in an overestimation of accidental factors for a long time, such as the myth of school myopia, for example. Studied from the viewpoint of the variability of the various causative factors, myopia at present appears to be a phenomenon resulting from a concordant or discordant variation of mathematically definable factors. Thus, the curve of the cornea, likewise the length of the ocular axis, may vary according to the tables of frequency established by Steiger. According to the combinations of these modalities, emmetropia, myopia, or hypermetropia, in given proportions, will result, without any evident or even admissible exogenous influence. Vogt studies the various ocular affections from this viewpoint, as well as the regulating influence exercised by selection in relation to the variations in the disturbance of the visual functions and those where correction can be obtained by proper therapeutic measures.

Operative Communication Between the Pericardium and Pleura in Cardiac Compression from Serous Inflammatory Exudates.—A. Läwen describes a procedure which assures a durable decompression of the heart by draining the pericardial fluid into the pleural cavity. In case of relapse, the pleural collection thus produced can be easily withdrawn by puncture. The opening between the two serous cavities is made at the most declivous part of the posterior pericardium a little to the outer side of the apex and to the inner side of the left phrenic nerve.

A New Operation for Ascites.—R. Sievers proposes, in order to assure the flow of ascitic fluid, to introduce through the diaphragm a fragment of the aorta taken from a cadaver. The fluid is thus drained constantly off into the left costodiaphragmatic sinuses, the flow being kept up by the respiratory movements of the diaphragm. The left pleura assures the regular absorption of the fluid.

On Tissue Regeneration.—A. Bier, in this, his eighteenth article on regeneration, considers the biology of the crevices of the connective tissue and tries to establish a relationship in the histologic make-up not only between the synovia, the synovial sheaths of the tendons, and serous bursæ, but also includes the connective tissue crevices with these serous membranes. In all these crevices a lubricating fluid exists whose composition is sometimes that of lymph, at others more viscous like synovial fluid, when the lining cells of the cavity secrete a fluid more mucous in quality. The secretion depends largely upon movements, pressure, or traction to which a given anatomical region is subjected, but these conditions are not absolutely essential for the secretion of mucus to take place. Bier brings forward examples of serous bursæ which formed, although the parts were not subjected to any mechanical irritation or movement and all that was necessary was the presence of a cavity maintained by keeping it filled with a physiological salt solution in order to transform it into a serous bursa. In this respect, Bier refers more especially to the removal of muscle or bone tumors where the resulting cavity after extirpation was filled with normal salt solution. As to the contents of these serous bursæ *a vacuo*, they consist of mucine unquestionably of the synovial type and can be distinctly distinguished from all other types of mucine.

On the Frequency of the Weil-Felix Bacillus.—L. Dienes comes to rather vague conclusions from the results he has obtained in hemocultures made from patients with typhus fever. While at the beginning of the war the Weil-Felix proteus was very frequently found, it would seem that at present it is much more rarely discovered. The presence of this organism appears to be closely related to a dissemination of disease by the Russians, and Russian prisoners did not show the presence of the proteus after they had sojourned for some time in Germany. The reaction of the Weil-Felix proteus is not a reaction of the specific bacillus of typhus, but rather a humoral change which arises during the evolution of the disease in circumstances which are as yet not clear. (The article is very confused and difficult of comprehension.—The reviewer.)

Consultation Institutes for Venereal Disease.—E. Finger proposes to form an organization of consultation posts with the object of intensifying the antivenereal struggle. This system is already working in Germany under the protection of the institutions of national insurance. The work to be accomplished by the consulting institutes is gratuitously to enlighten all persons afflicted with venereal disease as to the necessity of treatment, the degree of contagiousness of his or her affection, etc. As these institutes only have prophylaxis

as an object, the persons are sent to their own physician to carry out the treatment, the institutes' part being to advise the people and superintend their treatment by means of a system of information which puts the public into relation with the entire medical corps.

The Primary Treatment of Cerebral Wounds by Gauze Packing and Lumbar Puncture.—F. Demmer combines these two procedures and thus assures the best conditions for repair. The gauze packing prevents infection from taking place, as well as cerebral hernia, while repeated lumbar puncture prevents the occurrence of compression, etc. The wound being thus undisturbed, the process of repair begins at its edges while granulations spring from the bottom. Then a surface cicatrix forms which takes the place of the tissue destroyed without causing an irritant action (epileptoid), as is the case with cicatrices which are allowed to develop without these precautions.

The Potato Cure in Cardiac Hydropsy.—J. Lipiner, in this article continued from a previous issue, demonstrates the advantages of this diet. To explain the mechanism of its action, the writer invokes the small volume of the food, the relative restriction of liquid, dechloridization, and lastly, and above all, the potassium contents of potatoes. The action of this tuber is particularly diuretic and cardiotonic.

Brazil-Medico.

November 9 and 30, 1918.

Influenza in Brazil.—The Oswald Cruz Institute has naturally taken up the study of the pandemic as it affects Brazil and Dr. de Beauperaire Aragao publishes a preliminary report. The first cases to be reported in Rio were at once subjected to investigation at the Hospital di Misericordia, where they had been interned, and the research has been continued. The sputum finds have in no wise differed from those in Europe and North America. Pfeiffer's bacillus was present in less frequency than the pneumococcus, streptococcus and several other microorganisms. In 18 febrile cases blood cultures were attempted and the pneumococcus and *Streptococcus hemolyticus* were found in one case each. In experiments with small animals the inoculated sputum proved to be deadly, while sputum and other secretions when directly applied caused no reaction. The animals did not perish of any distinct malady but from various secondary infections due to the pneumococcus and other bacteria. In the same periodical for November 30, Drs. Da Cunha, Magalhaes and Fonseca publish a second communication from the Institute. A special small diplococcus has repeatedly been isolated from the secretions of the throat and has also been recovered by hemoculture. This organism was readily cultivated and inoculated into laboratory animals. Every attempt was made to secure pure cultures and the latter were also filtered. The material used in inoculation was also sown in certain culture media. Other inoculations were made with patient's blood. In monkeys the culture caused a type of fever without complications. The infection was transmitted in series from one guinea pig to others, always with the same result. Control experiments with Pfeiffer's germ gave negative results. The experiments with monkeys were simple but conclusive. One injection always caused after very brief incubation a fever of about two degrees Centigrade and when after recovery the inoculation was repeated the animal was found immune. Finally the monkeys could be immunized by a vaccine although these experiments have not been brought to a conclusion. In fine the work of the Institute thus far agrees in its finds with those of Nicolle in France, namely, that the infectious principle is a filtrable virus, but goes further in the recognition of the minute diplococcus as the cause of the pandemic.

Revista Española de Medicina y Cirugia

December, 1918.

Radium in Cancer of the Upper Air and Food Passages.—Botey has used radium for these conditions since 1906, having begun with cancer of the nose. In superficial cutaneous epithelioma of the latter, excellent results are obtained by the use of radium in sessions of 30 to 60 minutes each. Ordinarily half a dozen sessions at intervals of 4 to 7 days suffice for cure. Of intranasal growths treated the great majority were sarcoma or myxosarcoma. Direct applications were made with but little filtration. A Dominici tube enclosed in one of brass is supported with a tampon, and left in the nose for from 6 to 24 hours. After 3 or 4 sessions the sarcomatous tissue melts away. Instrumental removal of parts of the tumor may be used in association with radium. Recurrence sometimes occurs but may be retarded by radium. In endonasal epithelioma results are mediocre, and this is also true of the same lesion in the mouth with occasional exceptions. In the fauces the only growths to be benefited are fibroadenomas and adenomas. In malignant growths in this region any benefit is transitory. As for the larynx it has always been impossible to maintain a tube in its interior and the growths here are attacked through the skin. But results are poor and the author has spent much time in perfecting a technique in which intubation with or without tracheotomy serves for the introduction of a radium tube. He has made numerous applications of radium in this manner in which the external application is added as synergist. There is a conflict here because on the one hand the tolerance of the larynx for this treatment is limited and on the other hand large doses are in theory indicated. The reactions of the tissues are hostile to the development of the growth and favor autolysis of the cancer cell as well as production of fibrous tissue. It is believed, however, that radium sometimes favors recurrence and all in all the author would limit this treatment to small and circumscribed lesions. Radium after extirpation despite its alleged unfavorable action on extensive growths in the direction of recurrence is also held to prevent the first beginnings of recurrence, this duality being difficult to comprehend. In tumors of the esophagus radium is an excellent palliative. The author treats cases of this nature by the application of tubes with the aid of the esophagoscope for the space of about 6 hours, repeating after an interval of from 4 to 7 days. The size of the tube is increased progressively. The sound and catheter can be used as the growth recedes.

Boletina de la Asociacion Medica de Puerto Rico.

December, 1918.

Influenza in Puerto Rico.—Dr. Del Valle Atiles states that on June 13 last a Spanish steamer which sailed originally from Barcelona and touched at various other ports made port at San Juan. On board were five convalescents from influenza. The total number attacked had been thirty. The steamer had been in transit for thirty-two days, which apparently antedated the Madrid outbreak by a few days and seems to show that the disease could already have been present at Barcelona, Valencia, or Cadiz before it broke out at Madrid, as the boat had touched at the two last named. In the first authenticated epidemic of influenza in the United States in 1647 the disease was ostensibly brought from Valencia and hence known as Spanish catarrh. In the recent visitation San Juan was first attacked, then other cities and villages, and finally the rural districts. After the first visitation to the metropolis there was a recrudescence; by this time man to man transmission was no longer in evidence. At present there are only estimates of morbidity. It is computed that 100,000 victims were affected at the same instant in the island, or more than 8 per cent. of the entire population. Of 250 physicians in practice in the island at least 150 contracted the disease. The total number of people attacked during the entire epidemic is set down as 40 per cent. The total number of deaths from the disease in the month of November is known to have been at least 1,570. The total mortality on the island for 1917 for that month was 2,864, while for November of 1918 it was 5,284, or nearly double the first figure. These numbers justify the assumption of 4,000 deaths as the total tribute of the epidemic for Puerto Rico. It is by no means certain, however, that these figures comprise all the complications and sequelæ of the influenza, and a passage by the author seems to imply that at least many of these complications may not have been set down as grippe deaths.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 28, 1919.

DR. SOLOMON WIENER IN THE CHAIR.

Cerebral Hemorrhage Complicating Pregnancy.—Dr. EDWIN G. LANGROCK reported this case. He stated that the woman was a 1-para, 23 years of age, who was perfectly well until 7 P. M., on May 26, 1918, when she had a convulsion and fell to the floor. She became unconscious immediately and never regained consciousness. He saw the patient at 12.30 A. M., after her arrival at the Harlem Hospital, at which time her systolic blood pressure was 180, diastolic pressure 120, and pulse rate 54. She had Cheyne-Stokes breathing and her respirations were very poor. The catheter obtained only a few drops of highly colored urine. There was slight edema of the legs and more marked edema of the ankles. The whole right side of the body showed extreme spasticity, as did also the left lower extremity. The neck was slightly rigid. The left pupil was widely dilated, the right pin-point, and neither reacted to light. There was no corneal reflex. Babinski's sign and exaggerated knee-jerks were present on both sides. The lungs showed moist râles throughout, and the heart sounds were feeble and very irregular. Abdominal examination showed an eight and one-half months' uterus with floating head. Vaginal examination showed the cervix two fingers dilated, soft and thin. The fetal heart rate was 148, and of excellent quality. Lumbar puncture was extremely difficult and only a few drops of blood fluid were obtained. The diagnoses considered at this time were eclampsia and intracranial pressure. The latter was thought to be due to either: (1) Cerebral hemorrhage from eclampsia; (2) intracranial injury due to the fall following the convulsion (which might have been eclamptic in origin), or (3) to a medical cerebral hemorrhage as, for instance, the rupture of a blood vessel, the seat of endarteritis due to syphilis. The woman grew steadily worse, ceased to breathe at 3 P. M., and a cesarean section was immediately performed. The baby was resuscitated without much difficulty. It weighed 6 pounds 14 ounces, and left the hospital in three weeks in good condition. The perplexing questions were these: (1) Was the convulsion due to eclampsia or cerebral hemorrhage? (2) Was the cerebral hemorrhage traumatic, from her fall on the floor following her convulsion? (3) If the patient was not eclamptic and if the condition was not traumatic, what would produce a cerebral hemorrhage in a woman 23 years of age showing no signs of syphilis? The post mortem examination made by Dr. Cassasa of the Medical Examiner's staff showed the brain to be the seat of a most extensive hemorrhage, the ventricles all being filled with blood. The vessels at the base were hypoplastic. The heart was small and the aorta not of normal caliber. The whole cardiovascular system showed distinct hypoplasia. On this finding and several others the diagnosis of status lymphaticus was made. The liver and kidneys showed no evidence macroscopically or microscopically of eclampsia. The unusual features of this case were: (1) A case of status lymphaticus complicating hemorrhage and pregnancy with sudden death due to cerebral hemorrhage. (2) Postmortem cesarean section. (3) Intricacies of diagnosis involving eclampsia.

Rare Complication Following Normal Delivery.—Dr. ARTHUR STEIN reported this case for two reasons. First, because it was a rare and interesting case and, second, to secure perhaps some enlightenment in regard to the diagnosis. The patient was 31 years of age, the mother of two children, and had always been healthy. The husband had had gonorrhea several years prior to her first confinement but was perfectly healthy at this time. She went into labor on June 11, 1918, at 2.30 A. M. *without having been examined by any one.* Her confinement was regarded as most normal in every respect. Immediately after bringing the patient back to bed she complained of excruciating pains in the right sacroiliac region, and these pains promptly reached such a state of intensity that the slightest touch in that region caused her to scream with agony. Concurrent with these pains there was an immediate rise in temperature, starting at 101.6° and the following day reaching 104° F. The pulse was 140. The patient kept up this temperature and pulse with remittances, as in real sepsis, for nearly two months. At the end of July her temperature was practically normal, but her pulse was still around 130. At the onset of the sacroiliac pain the patient was carefully examined by an orthopedic surgeon who failed to find any lesion of the bones. On the supposition that there was some slight dislocation of the sacroiliac ligament she was tightly strapped with adhesive plaster. Examination of the patient's blood at the beginning of her illness showed *Streptococcus pyogenes.* She received antistreptococci injections for three weeks, as much as 20 to 30 c.c. a day. During the second week after delivery she developed a swelling of the left knee, which on puncture was found to contain a purulent material in which *Streptococcus pyogenes* was also present. At the end of July the patient was still unable to walk on account of the marked pain in the sacroiliac joint, but she was permitted to leave the hospital on crutches. *X*-ray pictures showed no abscesses of any kind and no destruction of any sacroiliac ligament. Numerous vaginal examinations were made during the course of the patient's illness, all proving negative, and the uterine secretions were also found to contain no signs of any virulent infection. Two weeks after leaving the hospital she again had a high temperature and pulse. When the speaker again saw the patient in the middle of September (three months after delivery) there was a large bulging mass in the right groin above Poupart's ligament. The right thigh was swollen and edematous in its anterior aspects, up to the middle of the thigh. Internal examination revealed the presence of a large abscess originating apparently in the sacroiliac region and working its way down and outward toward Poupart's ligament. The patient was then operated on with the result that after another six weeks of hospital care she was restored to perfect health. A large amount of pus was evacuated which contained *Streptococcus pyogenes* and also *Staphylococcus pyogenes albus.* The abscess was traced to the right iliac joint. Dr. Stein stated that he had reported this case rather in detail because he was uncertain whether this process was due to an old osteomyelitic focus in one of the pelvic bones or whether the whole process was due to some other cause. The surgeons with whom he had consulted were of the former opinion, there being no signs of any other infection and tuberculosis being practically outruled.

Three Cases of Unusual Intestinal Obstruction.—Dr. ARTHUR STEIN reported these cases. The first patient was a woman 24 years of age who gave an absolutely negative history. Six days before she was admitted to the hospital she was suddenly seized with cramp-like pains in the whole lower abdomen and back. These pains lasted for a day or two and then disappeared. They returned again the evening of her admission to the hospital and were accompanied by vomiting and high fever. Examination showed extreme but even distention over the entire abdomen, and marked tenderness on the slightest pressure; the pain, however, was more localized in the right hypogastrium, more especially over McBurney's point. It seemed that the right adnexa were enlarged and that there was a mass which might originate in them and have some connection also with the appendix. A tentative diagnosis was made of either an appendiceal abscess or a ruptured pyosalpinx. Upon opening the abdomen through a median incision the uterus and adnexa as well as the appendix were found to be perfectly normal. To their surprise the colon ascendens was seen to be extremely distended and a few fresh fibrinous bands were found gluing the small intestines together. The colon ascendens and transverse colon were then brought into view and three very small omental adhesions which held the ascending colon down were cut and ligated. The distention of the colon did not subside, however, after these bands were cut and it was therefore deemed advisable to inspect the whole colon down to the rec-

tum. The whole colon was therefore brought out of the abdomen, but no further adhesions were found. No signs of old inflammation or tuberculosis were found and the abdomen was closed. The patient had a rather stormy convalescence but after four days' constant effort on the part of the speaker and his assistants she began to improve and made a perfect recovery. This case was reported not because cases of intestinal obstruction were rare but because the origin was a rare one and the patient's history gave no clue to the condition that led up to the obstruction. The second case was that of a woman 28 years of age, married, who was admitted to the Harlem Hospital on January 26, 1918, in an extremely serious condition. Her former history was of no importance with the exception of the fact that she had undergone a laparotomy for uterine fibroid one year prior to her admission to the hospital. Since that operation she had never menstruated. Twelve hours previous to her admission to the hospital she was seized with severe abdominal pains and vomiting, her bowels moved, and her appearance was that of acute illness. The abdomen was markedly distended and extremely tender to the touch. No free liquid was found on percussion and no palpable masses could be felt. The blood examination showed 14,000 white cells, 89 per cent. polymorphonuclears, and 11 per cent. lymphocytes. A diagnosis of acute intestinal obstruction was made. Upon opening the abdomen some free fluid escaped. A loop of small gut was found firmly adherent to the pelvis and all the intestinal loops below this were greatly distended. This adherent loop of small gut produced a volvulus in such a way that a fold of mesentery tightly compressed the cecum. The cecum and appendix were found lying together underneath a fold of the mesentery to the left side of the abdomen. The appendix was quickly removed, and on freeing the adherent loop of intestine a small amount of fluid escaped from a pin-hole opening, which was closed with three purse-string sutures of linen. The volvulus was untwisted and the whole bowel carefully inspected, but no gangrenous areas were found. The bowel was returned to the abdomen and the abdomen closed in four layers, after a cigarette drain had been inserted. The patient received a stomach lavage of water, followed by sodium bicarbonate while on the operating table and one ounce of castor oil was administered through a tube. The patient's condition remained practically unchanged for two days after the operation. She vomited and was in great distress and all known remedies failed to induce bowel movement. Upon the fourth day following operation her condition became so alarming that a colostomy was done by means of a McBurney incision. In spite of all efforts the patient died. The post-mortem findings were caseous pneumonia in the right upper lobe with abscess formation in the center, acute localized peritonitis, necrotic ileum, and partial obstruction of the large bowel. There was also a specific aortitis. The third patient was also a woman 28 years of age, married, who had been operated on two years previously, the operation being gynecological, though none of the details were known to the patient. When the speaker first saw her she presented all the symptoms of acute intestinal obstruction. At operation, upon trying to excise an old laparotomy scar, a small loop of intestine, about fifteen inches in length, was found lying directly underneath the skin. The hernial ring through which this intestine must have escaped at the time of her previous operation was at the upper end of the old incision. It took the speaker exactly three-quarters of an hour to loosen the loop of intestine from the skin. He was then able to incise the hernial ring and to replace the intestinal loop which was not so black as to indicate resection. The excision of the hernial ring and the closure of the abdomen followed. The patient made an uneventful recovery.

Large Cauliflower Carcinoma of the Cervix in a Woman Twenty-three Years of Age.—Dr. ARTHUR STEIN reported this case. He stated that the patient was seen by him in September, 1918, when she gave a history of having had two children and one miscarriage. Menstruation had been normal in former years, but of late she had been bleeding profusely and constantly. About six months previously she had first noticed a slight irregularity in her menstruation. She went to a physician who gave her some internal medicine but did not examine her. Four weeks before the speaker saw her she consulted another physician who curetted her and diagnosed her case as one of uterine polyp. The patient seemed very sick and anemic. Upon introduction of the speculum into the vagina, a large, irregular, cauliflower-shaped mass originating in the cervical tissue was found. The diagnosis of cauliflower carcinoma of the cervix was easily established. Owing to the poor condition of the patient, it was not considered advisable to perform the radical (Wertheim) operation, but merely a total extirpation of the uterus and adnexa. Some glands around the common iliac artery on both sides were felt to be enlarged, but because of the poor condition of the patient and the deep seat of the cancer they were left behind, as their removal would have prolonged the operation considerably. The carcinomatous growth was about the size of a small child's fist, originated in the anterior cervical canal, and had destroyed practically the whole anterior lip, the posterior lip being apparently free. The microscopical report confirmed the diagnosis of carcinoma. This case was reported for two reasons: First, because of the extreme rarity of carcinoma of the cervix in a woman of that age and because of the malignancy of this type of carcinoma. The patient in this case was now dying of general carcinomatosis. The second reason was to emphasize the extreme importance of examining every woman who came to one's office giving a history of irregular bleeding without regard to her age.

Dr. JOHN O. POLAK stated that he had seen three cases of infection of the sacroiliac joint following labor during the past winter, and the interesting feature in these cases was that all three women were delivered spontaneously. It was difficult to say how infection reached the sacroiliac joint. An interesting point brought out in Dr. Stein's cases was that the temperatures were very similar to those of thrombophlebitis. A point in connection with infection of the sacroiliac joint was that in the presence of this condition there was pain on motion of the uterosacral ligament. In the three cases referred to the condition did not come on as quickly as in the case Dr. Stein reported; in these three cases the trouble came on in five, six, and eight days, respectively. In reference to the case of carcinoma of the cervix in a woman twenty years of age, they had had a case in a woman 23 years of ago who had an immense cauliflower growth. The uterus was removed and the patient subjected to radium treatment, yet within two weeks after the operation there was a recurrence and the woman died in six weeks. The entire pelvis was filled with the growth, showing the extreme rapidity of growth of this type of carcinoma in a woman of this age.

Extraperitoneal Cesarean Section for Contracted Pelvis.—Dr. GEORGE L. BRODHEAD reported this case, a primipara, who was admitted to the Harlem Hospital on Nov. 20, 1918. The patient was suffering from a marked toxemia, as evidenced by albumin and casts, edema of the legs and lower abdomen, and raised blood pressure. There was no headache, visual disturbance, or epigastric pain. The pelvis was slightly juxta minor and the head in R O position was just dipping in the brim of the pelvis. The fetal heart was strong and regular. The membrane had ruptured two days before admission, but the liquor amnii was clear and had no odor. The patient's temperature on admission was 102.5° F., the pulse 192.8. After a twenty-four hour test of labor, the patient being tired out and no progress having been made, except that the cervix was dilated, it was decided to perform extraperitoneal cesarean section. A medican incision was made from the navel to the pubis, but the bladder fold being much higher than usual, the incision had to be carried up one inch above the navel. The peritoneum was incised and the parietal peritoneum sutured to the uterine peritoneum for about six inches in the form of an ellipse. The uterus was incised, foul-smelling, green amniotic fluid escaping. The child was extracted by the breech in good condition. On account of moderate bleeding the uterus was packed with iodoform gauze and closed with the usual interrupted chromic gut sutures, and the peri-

toneum and abdominal incision closed in the usual way. For four days following the operation the patient's temperature reached 102° to 103° F., but on the fifth day it came to normal and remained so. The baby weighed 9½ pounds. Both mother and baby left the hospital in good condition.

Uterine Inertia.—Dr. GEORGE L. BRODHEAD reported this case. He said the woman, a multipara, was admitted to the Harlem Hospital on November 18, 1918. She had a normal pelvis and her previous labors had been short and easy. She stated that the membranes had ruptured spontaneously five days before admission and the night before she had bled a moderate amount. Pains had been present since the day before. No life was felt on this day, though the fetal heart was heard at 9 a. m. in the right upper quadrant. The cervix was long and soft and admitted two fingers. The presenting part could barely be reached by vaginal examination and no diagnosis of presentation could be made, though it was believed that the presentation was not vertex. Meconium-stained, slightly foul-smelling, fluid was draining away. The patient's general condition seemed to indicate no intrauterine hemorrhage and the diagnosis was inertia with dead fetus. The best treatment seemed to be the introduction of a large No. 5 de Ribes bag and then after full dilatation the method of procedure could be determined upon. There were no pains during the next eighteen hours and the patient was in good condition. At 4 P. M. November 19, the cervix was four fingers dilated, the head in R O P position above the brim, and there was a foul discharge from the vagina. As no progress was being made craniotomy was decided upon. The blades of the cephalotribe were applied but at once slipped off. The right foot was seized and easily brought out. Traction on the macerated foot failed to cause advance and the cervix was found thick and contracted about the thigh of the fetus. The patient vomited, had a chill, and a temperature of 102° F. (rectal). The pulse was rapid, and the woman complained of backache and was very restless. A hypodermic of morphine sulphate (one-quarter grain) was given and the patient put to bed, where she soon felt as well as before the operation. At 8.30 P.M. she had two hard pains and in five minutes the child was born. The fetus was not large, there was no hemorrhage and the patient was in good condition. There was a mild febrile puerperium, after which recovery was uneventful.

Dr. ABRAHAM J. RONGY took exception to the terming of the operation Dr. Brodhead described as extraperitoneal; it was really a transperitoneal operation. In an extraperitoneal operation the uterus was entered below the peritoneal surface. Sometime ago he had had to perform a cesarean section on a woman whose scar from the first cesarean section was situated below the umbilicus. He made the usual high incision and to his surprise found that the entire lower part of the anterior wall of the uterus was adherent to the lower abdominal wall, corresponding to the old scar. This brought out the point that if one did a cesarean section on a patient who had had a previous cesarean section and the scar was situated below the umbilicus, he should always bear in mind the possibility of the first operation having been of the transperitoneal variety and should not make a new incision but should go through the old one.

Dr. POLAK said that this point was well brought out by Dr. Green of Boston, who had reported the largest number of cesarean sections on one patient, through the same scar, namely, nine. He used Hirst's modification of the extraperitoneal, and probably the case referred to by Dr. Rongy was one of these. One objection to this operation was that a number of these cases became retroflexed. In this operation one was more likely to have leakage and hence he had abandoned it. He would consider that as Dr. Brodhead had described the operation it was transperitoneal rather than extraperitoneal.

Observations on a Series of Cases of Cesarean Sections Done at the Long Island College Hospital During the Past Six Years.—Dr. ALFRED C. BECK presented this communication in which he presented the detailed report of 57 personal cases, a morbidity study of 107 consecutive sections, and an improved technique for this operation. He concluded that cesarean section was at times the best means of obtaining a good result in serious obstetric difficulties other than marked disproportion. In his personal series of 37 cases only one mother died, and her death in all probability was due to eclampsia. When the operation was done before term there was great danger of losing the premature infant. It should not be performed in the interest of the child in such cases. There was a gross mortality of 3.8 per cent. in the entire series of 105 consecutive cesarean sections. The mortality of 16 cases previously handled on the outside was 16 per cent. The mortality in 86 cases treated wholly in the hospital was slightly over one per cent. The morbidity varied from 13 to 70 per cent. according to the absence or presence of conditions which governed morbidity. With this high morbidity we should be more fearful of mortality than the actual mortality in this series would lead one to anticipate. By completely sealing off the peritoneal cavity from the closed uterine incision a definite barrier was placed in the path of those infections which reached the peritoneum through the infection of the wound in the uterus. This was accomplished by the lapping of the peritoneal flaps as discribed by the author. This technique should be the one of choice even in elective cases. (See *American Journal of Obstetrics and Diseases of Women and Children*, February, 1919, p. 197.)

Dr. SAMUEL W. BANDLER said that the paper showed them a very distinct addition to the types of cesarean section, but there was one objection that must be raised, namely, that it was too difficult for the clean and safe cases, and possibly did not afford sufficient protection for the not clean cases as compared with extraperitoneal cesarean section. He doubted if it was as safe from the standpoint of infection as the extraperitoneal method, but in doubtful cases it was certainly more easily and readily done. The ordinary transperitoneal operation with the higher incision above the umbilicus and the much easier extraction of the fetus and placenta was, it would seem, the better method for clean cases. If the general practitioner could only be taught to be aseptic in his examinations, then even if a case had been in labor for hours and if the membranes had ruptured, the higher operation would be generally a safe one. Dr. Bandler said that while he did not wish to criticize there was one very important surgical feature that had been omitted in connection with the description of this operation, and he thought this criticism held with practically all the methods in use. This was a point of which he had wished to speak in connection with Dr. Stein's case in which he found the coil of intestine immediately beneath the skin of the abdomen. That meant that the peritoneal suture broke after the operation, which opened the peritoneum and also the muscle and fascia, and up came the intestine against the skin. Why, in doing a cesarean section, did they not unite the endometrium by a separate suture, just as in doing a gastroenterostomy or lateral anastomosis they must unite the mucous membranes? He could not understand why they had been so slow about this feature of the operation, for it was both surgical and safe, and made the rest of the cesarean section simple and easy. Dr. Bandler then described in detail his method of suturing the endometrium by which the cavity of the uterus was walled off completely from the subsequent field of operation. After this procedure the exposed raw surfaces made by the uterine incision scarcely bled a teaspoonful, especially since pituitrin was administered by hypodermic at the beginning of the operation. A series of No. 2 iodinized catgut sutures were then passed through the peritoneum and muscle of one side, taking in the thickness of the uterine wall but not going into the endometrium, passing out in the same way on the opposite side. The sutures were all prepared before the operation was begun, and thus five or ten minutes were saved, the whole procedure from the beginning until the patient was in bed taking scarcely thirty-five minutes. He did not cover the knots by uniting the peritoneum on the two sides since it put too great a strain on the peritoneum and was too likely to tear out. He passed a No. 1 or No. 2 chromic suture Connell fashion to the right and to the left between every suture previously placed in the wound. In his first cesareans the suture uniting the mucous membranes did

not pass through it but was passed through the muscle wall just above and parallel to it from side to side, like a subcuticular stitch. He thought that if either of these methods was followed out the results were bound to be better. If infection took place through the stitch punctures, we did not have simply a peritonitis; we had a metritis. Merely covering such an infection with peritoneum, as was done by Dr. Beck's method was not sufficient guard against the spreading of infection. Dr. Beck's method being done in the lower segment of the uterus, nearer to the cervix, was nearer to the area of infection if bacteria had entered the uterine cavity. As to a choice between Dr. Beck's method and the extraperitoneal route, he was seriously in doubt whether in the cases that were not aseptic it was safe to follow his method without some form of drainage. If he were to follow his method in a doubtful case he would prefer drainage.

Dr. WIENER asked those who continued the discussion to include Dr. Bandler's remarks as a part of the subject under discussion. It would appear that Dr. Bandler's suggestion was a return to an older method which they had largely abandoned because it had been considered a bad practice to have the sutures enter the uterine cavity, just as in a complete laceration of the perineum it was not advisable to have the sutures enter the lumen of the rectum.

Dr. BRODHEAD asked if, in performing this kind of cesarean section with the low incision into the uterus, one must convert a vertex into a face presentation or it was necessary to use the forceps, whether it would not be safer to wait before giving the pituitrin until after the extraction of the child, since one sometimes had difficulty in getting the child out after he had given pituitrin before the usual incision. He also asked Dr. Bandler why the suture of the mucous membrane stopped the hemorrhage. He thought it would seem more reasonable to suture the muscular layer. He agreed with Dr. Bandler that in cases in which frequent examinations had been made he would rather do one of the extraperitoneal operations, feeling that it was safer, and he questioned whether in any clean case this operation had advantages sufficient to make up for the increased time it took to do the operation in that particular way.

Dr. Bandler replied that he did not suture the endometrium because it stopped bleeding from the uterine wound; it kept the blood which was being poured out into the uterine cavity from going into the wound and made the remainder of the operation exceedingly simple. When he first developed this technique he passed a continuous suture close to the endometrium all the way through the length of the wound and the remaining sutures were passed as above. He thought the separate union of the mucous membrane an important step in the operation. He believed the secretion from the uterine lining, if it passed up between the muscle layers, might interfere with the union of the muscularis and might digest the stitches, which was another reason for uniting the endometrium, as the first step of repair after incision and delivery.

Dr. POLAK said he did not see what happened to the endometrium after Dr. Bandler's way of suturing, how he took it in the suture. He must go through the decidua and pass through the endometrium and it seemed to him that he would thus make an avenue of infection instead of preventing it. The reason he gave up the other method was because the uterus became fixed high up and on reopening the abdomen one invariably found adhesions to the uterine scar and the abdominal wall in cases operated on by the other method.

Dr. I. C. RUBIN suggested that the reason the method of suture of the mucous membrane described by Dr. Bandler was abandoned might be answered by saying that to-day the surgeon operated in an aseptic field, while in former days any laparotomy was a serious danger. He thought that the method described by Dr. Bandler was less likely to be followed by infection than the method more generally employed, and that the hemostasis that it afforded also conduced to good results, and for these reasons it recommended itself rather highly.

Dr. RONGY expressed the opinion that there was no question but that Dr. Beck had brought them something new to-night. However there were a few points that must be considered in conjunction with his operation in its relation to future pregnancies. He thought that possibly there was a likelihood of more frequent spontaneous rupture of the scar when it was situated in the lower portion of the uterus. The abdominal incision below the umbilicus had also the disadvantage that postoperative hernia took place more readily in the lower portion of the abdominal wall than in the upper portion. As to the suggestion of bringing the catgut through the mucous surface in order to control hemorrhage from the uterine cavity, he felt that the danger of creating a source of infection from the uterus was too great and at all times suturing material should be kept from the uterine cavity during the performance of cesarean section.

Dr. POLAK stated that he had had about fifteen Krönig operations and he had been able to close the uterine wound completely in all but one. He thought they did not get infection from the spill of amniotic fluid but they did get it from the inside of the uterus. They had had seven autopsies following cesarean section and every one had presented the same picture, that was the uterine wound had been more or less open and the suture cut, and the infection had followed the suture tracts from the inside of the uterus outward. It seemed to him that Dr. Beck's operation was nothing more than an improvement on the Krönig technique. This operation had not the disadvantages of the extraperitoneal operation, which was a much more difficult operation technically to do. One point of importance was that they got the incision low and there was a little trick of accomplishing this. After they threw the bladder up against the pubis they took a gauze pad and placed it against presenting parts and threw the uterine segment up, and this in conjunction with the Trendelenburg position enabled one to make the incision in the lower uterine segment. Convalescence after this operation had been very smooth, there being less intestinal and less abdominal disturbance than in the usual cesarean operation.

Dr. BECK, in closing, related a part of his cesarean experience in refutation of Dr. Bandler's remark that this precedure was too difficult for simple cases and not safe enough for questionable cases. He said he thought he had done at least 35 operations according to the technique described by Dr. Bandler, with the exception that the endometrium was carefully avoided in the suturing of the wound. He felt that closure of the endometrium was accomplished by the deep sutures which passed through the entire thickness of the muscle down to, but avoiding, the endometrium. As most of these patients came from the prenatal clinic, the usual factors which rendered cesarean section dangerous were absent, that was, the operation was performed as an elective procedure or when a test of labor was given vaginal examinations were not made. After reviewing his results from the standpoint of morbidity, he concluded that even in elective cases there was danger of peritonitis and every effort should be made to prevent this complication. As was shown in this report of 105 cases from 13 to 70 per cent. had a definite marked morbidity. A suturing of the endometrium as suggested by Dr. Bandler, it seemed to him, would favor the extension of infection to the uterine wound, as the suture passed into the uterine cavity. From the results of this procedure, as shown on examination of the few patients upon which the operation just described had been performed, it would seem that there actually was a complete peritonealization of the uterine wound, as in each instance the uterus was in good position and no evidence of adhesion was noted. Concerning what Dr. Brodhead had said, it used to be their custom to give pituitrin just before they started the abdominal incision. They now gave the injection just before they started the uterine incision. As a result the incision was completed and the child extracted usually before the drug had taken effect. By giving it in this way they felt that it did not interfere in the way suggested by him and at the same time it greatly aided in the control of hemorrhage immediately following the operation. As to Dr. Rongy's remarks, they seldom heard of a ruptured vaginal cesarean section scar. The incision in the operation he had described passed through prac-

tically the same tissue as did that in a vaginal cesarean section. One might therefore expect results with regard to rupture similar to those in vaginal cesarean section.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 11, 1918.

DR. HERBERT B. WILCOX IN THE CHAIR.

The Active Immunization of Children Under Eighteen Months of Age with Diphtheria Toxin-Antitoxin.—Dr. ABRAHAM ZINGHER presented this communication. He stated that the presence of diphtheria in civil communities presented an important problem and quoted statistics showing that from 1900 to 1910 there was an average of 1900 deaths annually from diphtheria, and that of this number 77.5 per cent. occurred among children under five years of age. The mortality from diphtheria was higher than that from measles and scarlet fever combined. Attempts to isolate and control carriers and the administration of antitoxin had failed to control the disease as it had been hoped they would do. After reviewing the work they had done on the Schick test for the past four and one-half years and the conclusions they had reached, Dr. Zingher presented a chart showing the way in which 101 subjects that gave a positive Schick reaction, and were injected with toxin-antitoxin, gradually came to give a negative reaction. Three weeks after the first injection of toxin-antitoxin, 30 per cent. had become immunized, and 70 cases had failed to respond. A week later still more had responded and gave a negative Schick test. At the end of seven weeks only 19 were found to be slow in developing immunity. Of the 19 who were left in the institution at the end of eleven weeks, finally, all showed a negative Schick test. In making an investigation as to the duration of active immunity the speaker visited 30 small institutions and gained permission to test the children and to administer the immunizing doses of toxin-antitoxin to those that reacted positively to the Schick test. Charts showed how these children gradually developed immunity. When the three doses of toxin-antitoxin were given, 85 to 95 per cent. responded by developing a negative Schick reaction, and a year later retests showed that this active immunity still persisted. Later a retest at two and one-half to three years showed that the immunity persisted. This work had been carried out not only in institutions but in schools, with the consent of parents, and in milk stations and day nurseries. Interesting and important results were obtained at the New York Foundling Asylum, where children ranging in age from a few weeks to eight years were tested and immunized. As had previously been pointed out, the infants of immune mothers were often immune at birth but generally lost this immunity later during the first or second year of life. The charts showed the results in three groups of mothers and infants. In the first group the mothers and infants from two to six months of age were both immune; they were retested six months later, and, while the mothers were still immune, the infants had become susceptible, as shown by their giving positive Schick reactions. In the second group of cases the mothers were immune and the infants, from six to nine months of age, susceptible. The susceptible infants were given toxin-antitoxin, and later the Schick test showed that they had become immune. In the third group both the mothers and infants had become immune. Dr. Zingher said that in his experience he had never found any instance where the mother was susceptible and the young infant immune. From this study the following conclusions were warranted: (1) Many children are susceptible at birth or become so shortly afterward or during the first year of life. (2) Morbidity and mortality from diphtheria were highest from the first to the fifth year. (3) All children, both negative and positive reactors, under eighteen months of age should receive three immunizing doses (each 0.5 c.c.) one week apart. (4) Of the children over eighteen months of age and of youths and adults only those should be immunized with toxin-antitoxin who gave a positive Schick reaction. To these susceptible individuals three doses, each 1.0 c.c., were given, one week apart. They found that young children were very likely to take toxin-antitoxin mixture without showing a local or systemic reaction. The susceptibility to a foreign protein developed at a later period in life; none of the unpleasant reactions that occurred in older children and in adults manifested themselves in young children. The immunity produced by the toxin-antitoxin seemed to be fairly constant. The toxin-antitoxin might be used as a general prophylactic measure or it might be used to control outbreaks of diphtheria. By the application of the Schick test and diphtheria toxin-antitoxin, diphtheria had been practically stamped out in one institution in this city. In another institution the work was carried on during a period of over eighteen months and it was found that the children who were negative at the first test continued to give a negative reaction at subsequent tests. Those reacting positively were given toxin-antitoxin and a large percentage of these became immune. From observations made during an outbreak of diphtheria in one institution it was evident that toxin-antitoxin alone could not be depended upon where the outbreak was extensive and threatened to spread. The stamping out of this epidemic in spite of the presence of a large number of carriers afforded a very striking illustration of the control of the situation that the Schick test gave in the presence of an outbreak of diphtheria in an institution. The immunity developing from toxin-antitoxin was slow in appearing, and was therefore not a reliable safeguard in hospital wards where children were crowded together and suffering from various contagious diseases, but in institutions where diphtheria was more or less constantly present and clinical cases and bacillus carriers readily appeared, the combined application of the Schick test and active immunization had given most successful and encouraging results.

Dr. WILLIAM H. PARK stated that he and Dr. Zingher and those helping them had started several years ago with the mild hope that had now grown into an expectation and almost a belief that an entire population could be immunized to diphtheria. They had tried this in a number of institutions and had found that they could succeed in producing a lasting immunity in children who did not develop a natural immunity. Active immunization with toxin-antitoxin would start the process of immunization in a susceptible individual, and when the process had been started the individual would continue to make antitoxin and finally in some way a natural immunity took place. They had now refined the toxin-antitoxin so as to get rid of some of the protein substances derived from the bacillus, which caused in some individuals marked reaction. With injections of this refined preparation children would probably develop no deleterious reaction and, feeling sure on this point, we need have no hesitancy in urging general immunization against diphtheria. The Health Department Laboratory would furnish toxin-antitoxin and send a physician to make the injections when this was desired. They hoped to get a large group of infants and young children who had been actively immunized and to follow them from year to year, and they would be glad to have institutions co-operate with them in this work.

Dr. ALFRED F. HESS stated that the Schick reaction combined with the toxin-antitoxin injections had entirely changed the situation in regard to diphtheria in the institution with which he was connected. Previous to the introduction of this test they had diphtheria every year and always lost one or more children. About five years ago they began using the Schick test and thus dividing the susceptible children from those that were immune. In this way, by using the von Behring toxin-antitoxin method for immunizing all susceptible children, they had been able to control diphtheria in an institution having four hundred children. They had found that for one and one-half or two years 98 per cent. of the children had retained their immunity. They had found that it was not enough to test the children every year to know which were immune at one, two, or three years. They found that 15 per cent. became susceptible between the time of birth and the age of one year; 10 per cent. became susceptible during the second year; 5 per cent. during the third year, so that one must

watch very carefully during that entire period. They had had no case of diphtheria in any of these children in the last three years and thought this a very excellent result. As to the untoward results, there were three of four instances in which a reaction occurred after the administration of the immunizing dose of toxin-antitoxin, but in each instance the disagreeable symptoms were of short duration. He felt that in their institution they could not get along without the Schick test and toxin-antitoxin immunization.

Dr. ZINGHER, in closing, stated that they had given thousands of injections and had found that the younger the child the less likely it was to show a reaction to the toxin-antitoxin. In the thousands of injections he had given he had seen no instance of collapse or shock immediately following an injection. Even the history of the case reported by Dr. Hess indicated that the toxin-antitoxin might have had nothing to do with the temporary indisposition of the child. In one milk station the death of a child twenty-four hours after a Schick test was attributed by the family and the nurse to the Schick test. From their large experience with thousands of properly performed Schick tests they knew that such an occurrence was practically impossible. To emphasize the points brought out in this communication, Dr. Zingher again stated that the best way apparent at the present time for controlling and stamping out diphtheria from our communities was actively to immunize all children under eighteen months with toxin-antitoxin. The older children should be tested with the Schick reaction and only those immunized who gave a positive reaction and were susceptible to the disease.

A Psychological Study of Stealing in Juvenile Delinquency.—Dr. L. PIERCE CLARK presented this paper, in which he made no attempt to consider the so-called benign types of ordinary stealing, nor was emphasis placed on fanciful stealing, such as the cleptomanias. On the whole the main characteristics of the persons here considered were stealing money and consciously committing other antisocial acts of a petty sort, mainly as a consequence of having no well grounded sense of property rights. Usually these individuals showed predominantly many other poor adaptations to authority and law from earliest life, or they appeared unable to grasp thoroughly the importance of making the proper submission and compromise with parental discipline. There were some investigators who looked for the root of these trends entirely in the make-up of the youth himself, accounting him either a moron, a subinhibited mental defective, one antisocially inclined, or a psychopathic inferior, whatever that term might mean. Others greatly favored the idea that the parents or home environment were largely responsible for the development, if not for the actual implantation of the unruly or immoral traits of character. Usually neither group failed to indict the family stock for the delinquents found. When one undertook to investigate a series of such youths he was impressed by the fact that there were many more subtile forces at work than those usually obvious on the surface. Healy, in his investigations of mental conflicts and repressions in delinquent children, analyzed the acts of stealing money to sex delinquency and the incomplete mastery of the latter. In a long series of cases he found surprisingly often concealed sexual conflict as well as defect in parental discipline and lack of proper filial-parental relations. However, he mentioned no case in which antagonism to the father and desire for childish revenge upon this parent was the cause for stealing. Such a case was recently seen by the writer. This was a boy who for several years had stolen and played truant from school. The mother herself had become embittered because of her marital troubles and had gone to live with her mother. The boy stole so much from the grandmother and her immediate family that the mother had to take him elsewhere. The boy's great fault was in concealing his thoughts and daily activities from the grown people. After the more obvious faults in his home and school life were set right and the boy was permitted certain liberties and pleasures, his conduct improved, yet he still lied and was sly. A frank talk with this boy showed that he failed to make any good compromise with discipline and authority. Dr. Clark related several similar instances and also cases in which the delinquency was more complicated and seemed in part due to inability to adjust properly to the revolt at puberty. In one case the cause seemed to lay in a latent homosexual complex. From a study of these cases the writer believed that one might fairly infer, when the act of stealing occurred without apparent motive, at least sufficient for the offense as ordinarily found, that it was probably unconsciously conditioned upon either a defect in adaptation to authority, to sexual conflict and repression at puberty, or it was a vicious homosexual theft substitution for the offender's own sex. The line of therapeutic procedure was obvious in all these cases, that was, explanation by analysis, conscious guidance, and a sympathetic aftercare and training. The enormous demand and difficulty of sublimation in the homosexual victim of the theft habit made correction extremely difficult. In fact it was to be doubted whether the homosexual was ever able to sublimate sufficiently to keep him from social conflicts or from a neurosis more or less dominant through his life. One could not too forcibly insist upon the importance of studying the child's adaptation to parental authority when delinquency began at a very early age as a basis for adjustment to all law and order in the future life of the individual. Sufficient data were at hand to warrant the statement that in the infant mind one of the earliest conceptions of reality was impingement of its desires by the parent. The magic signals of crying and gestures did not move the parent to gratify the child's wish. In the persistence of this feeling of unrequited longing no doubt the child began to scrutinize with increasing wonder the reason for noncompliance on the part of the parent, and more or less rapidly interpreted it in terms of selfishness or the self-satisfied possession of things and powers which enabled the person calmly to resist the child's frantic demands. Soon the parent's belongings were taken as symbols of the parent's potential self-sufficiency. It was not a far step to the further exercise of power for the child's satisfaction in gratifying his personal appetite in stealing fruits, or committing forbidden excesses which he believed the parent had unrestricted opportunities to enjoy. This seizing of the parental power and privilege advanced to new forms of covetousness and conquest, namely, that of possessing the magic symbol, money. In conclusion, it might be said that, even when the child's defective adaptation to authority and property rights were made clear, there were possibly other and still more genetic reasons for this early conflict, namely, the latent infantile desire to usurp the place of the father and all its possible prerogatives. While one need not neglect the study of the adult life of criminals, and especially the causes of recidivism, even there the adult pattern of the antisocial acts would probably be found to embrace in greater part the distorted mechanism of the primary life fault of early life. Dr. Clark, in closing, added his suggestions to those of Dr. Healy and Dr. Glueck to the end that the intensive study of antisocial behavior of the juvenile delinquent might enable us to correct not a few such faults before a fixed formation of habits and character had rendered the offender so hopeless in adult life.

Dr. BERNARD GLUECK referred to his work with the adult offender in a state prison, which had made him feel that the best results in regard to the study of the fundamental causes of misbehavior would be obtained outside of penal and correctional institutions, and certainly much earlier in the life of the individual than was possible in a state prison. There had to be established, first of all, a kind of relationship between the examiner and the prisoner, such as obtained between the patient and the physician, and this was still an ideal in most institutions. Those who were doing clinical work with the prisoner had fallen into the habit of assuming that in diagnosing the personality they had defined the problem of causation of the criminal act. This was true in some cases, but in the majority of instances the mere definition of the personality did not clear up very much the question of causation. It was in the patients who came to them spontaneously, because of some difficulty, and because they started out with the idea of establishing the proper kind of relationship with the examiner, that they obtained the most helpful clues as regards

causation, and not in the course of routine examination. Dr. Clark's paper threw exceedingly illuminating light on some of the origins of misbehavior. They had felt in a number of instances that it was just this revolt to parental authority in the youngster which remained unadjusted, that might lead to the transfer of the same feeling against authority in general, and to the easy development of a peculiarly paranoid outlook on life, which in its fully developed form might be called an anti-social grudge. In some instances this outlook on life assumed a more or less passive character while in others it assumed an active rôle, and the individual, aggressively antagonized the social order or customs. Occasionally a man left prison and frankly admitted that he had no intention of changing his former anti-social habits, actively resented any help or guidance toward rehabilitation, and seemed to derive considerable satisfaction from the coddling of his attitude toward society at large. There was also not much doubt concerning the relationship of disorders in the sexual life or instinct to misbehavior. The efforts at adjustment which certain individuals made when finding themselves confronted with a disturbing situation in their sexual life occasionally assumed an antisocial trend, and the crime might be looked upon as either a defense reaction or faulty method of adjustment. After relating such an instance coming under his observation Dr. Glueck expressed the opinion that studies like Dr. Clark's ought to be encouraged for he believed that an intensive psychoanalytic study of a few cases had the capacity of throwing far more light on the problem of causation of crime than the mere objective clinical study of even a very large number of inmates could ever hope to do.

Dr. Helen Montague of the Psychopathic Clinic of the Children's Court stated that during the last fifteen months they had had 1100 children in the clinic of the Children's Court, of whom 474 were accused of stealing. This would go to show that stealing was one of the most common of the crimes that they were investigating. It had been their course to believe that there was something wrong with these offenders and one was inclined to think at first that they were feeble-minded. About 27 per cent. of this number were feeble-minded; about eight per cent. were psychopathic, and about 28 per cent. belonged to that class which had been designated as constitutionally inferior. This percentage of feeble-minded was rather low; it was generally estimated that among those who were in the habit of stealing about 30 per cent. were feeble-minded. However, the mental condition seemed to have very little to do with stealing. About 50 per cent. of those brought to the Court for stealing had a very poor environment. About 80 of those arrested for stealing were girls; the remainder were boys. The speaker cited in detail the history of several instances of stealing in which mental conflict was a factor. Often the boys first committed theft simply from a spirit of adventure, or to have a good time, and later on acquisitiveness entered in when they found that they could profit by the things they had stolen.

Dr. Edith Spaulding of the Laboratory of Social Hygiene expressed the opinion that Dr. Clark's paper was a valuable contribution to the study of larceny. It was through such intensive studies as these that progress was actually going to be made in the knowledge of antisocial acts. One part of Dr. Clark's paper that had particularly interested the speaker was the variety of types and causes which he brought out in his several cases. It was perhaps a tendency of the times to believe that delinquencies of various sorts could be reduced to a single simple formula by way of explanation and it was perhaps equally true that each reformer had a pet panacea which he advocated above all others in the reconstruction of individuals. There were doubtless many different causes of stealing, some of which Dr. Clark had so well described. The only one panacea which could be recommended was the analysis that had been used in his cases which permitted the fullest knowledge possible of each case and itself suggested the methods needed in the individual's reconstruction. Among the larceny cases among the psychopathic women at Bedford, there were some who had shown unusual resistance to sex temptation and others who had been unable to adjust themselves to the sex requirements of married life or its equivalent. In these cases the relationship of the stealing to the sex maladjustment was not always clear in its origin. Many times, however, the stealing appeared to be due to childish standards of property which persisted in adult life, perhaps due to, or, at any rate, accompanied by a lack of development in other ways, one of which might be undeveloped or suppressed sex emotions. Both manifestations of immaturity might be the result of a series of maladjustments dating back to early childhood which had blocked development. Situations had not been met because of childish attitudes and fears or repressions. The way of least resistance had, therefore, always been chosen.

The sense of "mine" and "thine" was, it seemed, to a large extent an acquired characteristic of adult type, resulting from a realization of social rights and social standards. The appropriation of articles in the family during childhood was a very different matter, legally, when continued in the larger social family in adult years, no matter how similar the fundamental attitudes might be. After citing in detail a case which illustrated the association of stealing with sex maladjustment, the speaker said that in studying the origin of stealing, it seemed as though in many instances it might be the infantile expression of a primitive instinct of an acquisitive nature such as was found in animals as well as in primitive man. Such an instinct might suddenly appear with the same dominating power which the sex instinct manifested in maladjusted individuals. The appearance of this primitive acquisitive instinct as a habit might be likened to a malignant growth which represented tissue as harmless and as common in the embryo as was stealing in the child, but became an undesirable and even a destructive factor when it ran wild in the adult make-up.

Dr. Anne T. Bingham related a recent discussion which she had heard on the subject of stealing by several prominent psychiatrists and criminologists. They all confessed to having stolen as children and stated that stealing was their first delinquency. This was suggestive and indicated the desirability of having a thorough study of this form of delinquency. Making a thorough study of this subject did not mean making a classification, and fitting the individual to that classification, but it meant a thorough study of the make-up of the individual. The New York Probation and Protective Association had been studying this problem in the girls with whom it came in contact. They had found that stealing was very frequently associated with sex delinquency. It was interesting to hear how these individuals rationalized their conduct to themselves though they did not always succeed in doing so to those who studied them.

Dr. Clark, in closing, expressed the opinion that what was needed was the practical application in psychiatry of that principle which had added so much of value to the science of internal medicine, namely, that every case should be studied singly. Hitherto we had studied crime as an act, not from the standpoint of the individual criminal. The work that had been done at Sing Sing by Dr. Glueck and in Boston by Dr. Healy demonstrated that the problem offered by crime must be approached by the intensive study of the individual. As we all knew, stealing and lying were decidedly common traits in all families, and it had been suggested that they be put down in the family code. But when lying and stealing became a habit with the child, it was difficult for him to adjust himself to the codes of society in later life, and it was the failure to make this adjustment that led the delinquent to such disastrous results. It was not that these acts in themselves were essentially asocial in children; it was the continuance of them in later life that gave us the greatest concern, and just why these traits failed to be suppressed or transformed into healthful activities would be a great problem for future investigation. The study of the individual in his effort to meet these adjustments would be a great advance, Dr. Clark said, over the present archaic method of first making a classification and then endeavoring to fit the individual delinquent into a certain class, and would place criminology on a more scientific basis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

California State Board of Examiners.

Sacramento, October 22-23, 1918.

ANATOMY AND HISTOLOGY.

(Answer ten questions only.)

1. Discuss anatomy of the superficial lymph glands usually involved in the secondary phases of lues.
2. Describe briefly the gross structure of the pancreas and its topographical anatomy.
3. Discuss the structure and relations of the various tissues penetrated in making a lumbar puncture.
4. Describe fully the histology of the skin of the ala nasi and compare with that of the eyelid.
5. Discuss the attachments and action of the pectoralis minor.
6. Discuss briefly the contents of the axilla and their relations.
7. Describe briefly the portal circulation.
8. Describe the dorsalis pedis artery and its relations.
9. Name from without inward, the coverings of the testicle.
10. Describe the microscopic structure of the ovary.
11. Describe fully the frontal sinus.
12. Briefly describe the heart and its topographical anatomy.

PHYSIOLOGY.

(Answer ten questions only.)

1. Discuss the retina and its physiological properties.
2. Discuss the physiology of the blood leucocytes.
3. Describe general physiological conditions influencing blood pressure and blood velocity.
4. Discuss the contraction wave of the heart.
5. Discuss vaso-motor regulation and explain its importance in relation to function of organs, giving three examples.
6. What is intracranial pressure? Discuss the causes and effects of variations in this pressure.
7. Discuss the negative pressure prevailing in the thoracic cavity. Explain what influence it has on the organs in the mediastinal space.
8. Describe how the respiratory reflexes are protective, give examples and trace the reflex.
9. Discuss the events that occur during a single cardiac cycle beginning with the closure of the semilunar valves.
10. What relation should the quantity of vegetable food including starch and sugar bear to animal food consumed in 24 hours?
11. Describe myenteric reflex or the law of the intestines.
12. Describe the nervous mechanism of vomiting.

MATERIA MEDICA, THERAPEUTICS, PHARMACOLOGY AND PRESCRIPTION WRITING.

(Answer ten questions only.)

1. What is incompatibility in medicine and what are the different kinds of incompatibles? Give examples.
2. Outline the treatment of a typical case of "Spanish Influenza" in a young adult. Write prescriptions for all drugs used.
3. Discuss briefly the indications and contraindications for the use of digitalis in affections of the heart.
4. Describe pituitary extract and discuss briefly its uses and abuses.
5. Describe origin, physiological action, and give dose of salicyclic acid.
6. Why is adrenalin used in solutions of novocaine for local anesthesia?
7. Give physiological effects, therapeutic application and mode of administration of oxygen.
8. Name drugs which administered to the mother produce a therapeutical action in the nursing child. What substances increase the flow of milk and what decrease it?
9. What is dichloramine-T? Describe its methods of application and its effect in infections.
10. Give treatment with prescription (written without abbreviation) for acute rheumatism.
11. Outline in detail the non-operative treatment of acute cholecystitis.
12. Discuss psycho-therapy, its relation to and its uses in the modern practice of medicine.

ANSWERS.

ANATOMY AND HISTOLOGY.

1. The inguinal glands are situated between the two layers of the superficial fascia and consist of two groups: (1) A horizontal group, roughly parallel with Poupart's ligament, and (2) a vertical group lying along the upper part of the internal saphenous vein. The superficial glands are about ten to twenty in number. Since syphilis is a *general* infection, and not a *local* disease, any lymphatics may be involved. The above, with the epitrochlear and the cervical, are among those most commonly involved.

2. The *pancreas* is long and irregularly prismatic in shape; it has been compared to a human or dog's tongue. The right extremity is called the head, which fits into the curve of the duodenum; the left end is called the tail and reaches to the spleen. The stomach lies in front of the body of the pancreas, and the transverse colon and its mesentery crosses the lower end of the head, which is also in relation to the superior mesenteric vessels. Behind the pancreas are the superior mesenteric artery and vein, portal vein, inferior vena cava, aorta, crura of diaphragm, left kidney with its suprarenal capsule. Below are the jejunum, the duodenojejunal junction, and the splenic flexure of the colon. Above the neck is the pyloric end of the stomach. The pancreas lies across the front of the first and second lumbar vertebræ, behind the stomach, and in the epigastric and left hypochondriac regions. Its canal is the duct of Wirsung, which extends transversely from left to right and opens into the duodenum in common with the ductus communis choledochus.

3. In making a *lumbar puncture* the following structures are penetrated (in order): Skin, fat and fascia, latissimus dorsi muscle, the posterior layer of lumbar fascia, the erector spinæ mass of muscle, ligamentum subflavum, spinal dura, and arachnoid.

The *skin* consists of (1) epidermis and (2) dermis. The *epidermis* is made up of three principal layers: (*a*) The horny layer, or *Stratum corneum*, is the most superficial and consists of layers of flattened cells, which are dry and horny without any nucleus: (*b*) the *Stratum lucidum*, composed of several layers of nucleated cells, which are more or less indistinct, and in section appear as an almost homogeneous layer; (*c*) the *Rete mucosum*, or Malpighian layer, contains, in its upper part, layers of "prickle" cells, and its inferior layer consists of a single stratum of columnar cells. Pigment is principally found in the lowest layer.

The *dermis*, or true skin, is made up of an interlacing network of connective tissue, formed of white fibrous tissue, yellow elastic tissue, corpuscles, vessels, and nerves. In some parts of the body, as in the skin of the scrotum, perineum, penis, the cutis vera contains unstriated muscular fibers. There are also small muscular fibers in connection with the hair follicles. Beneath the skin the subcutaneous tissues contain abundant adipose tissue.—(From Ashby's *Notes on Physiology.*)

The *fascia* is an inelastic fibrous membrane, composed mainly of white fibrous connective tissue.

Voluntary muscle is composed of long, narrow fibers, with cross striations, surrounded by sarcolemma, and has many nuclei beneath the sarcolemma.

The *dura* consists of dense fibrous tissue containing connective tissue cells.

The *arachnoid* is composed of areolar tissue with few elastic fibers, and is covered by a layer of endothelium.

4. The skin of the *ala nasi* is of the structure given in question 3, but it is thicker than usual and is furnished with an unusual number of sebaceous follicles. It is firmly connected to the underlying structure.

The *skin of the eyelid* is loosely connected with the underlying muscle, it has no fat in its subcutaneous tissue, and the sebaceous glands are very small; the skin is thin.

5. The pectoralis minor has its *origin* in the upper border and outer surfaces of the third, fourth, and fifth

ribs, near the anterior extremity; also from the fascia which covers the external intercostal muscles in that region. It is *inserted* into the coracoid process of the scapula, where it is connected with the origin of the coraco-brachialis and the short head of the biceps. *Action*: It draws the scapula downward and forward and depresses the point of the shoulder; acting from the insertion, it elevates the third, fourth, and fifth ribs (as in forced inspiration).

6. Contents of the axilla and their relations: "It contains the axillary vessels, and the brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymph nodes, all connected by a quantity of fat and loose areolar tissue. The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axilla, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axilla, in contact with the pectoral muscles, and along the anterior margin are the thoracic branches of the axillary artery, and along the lower margin of the pectoralis minor the long thoracic artery extends to the side of the thorax. At the back part, in contact with the lower margin of the subscapularis muscle, are the subscapular vessels and nerves; winding around the outer border of this muscle is the dorsalis scapulæ artery and veins; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder. Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation, viz., the long thoracic or external respiratory nerve, descending on the surface of the serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercostohumeral nerve or nerves, passing across the axilla to the inner side of the arm."—(Gray's *Anatomy*.)

7. *Portal circulation:* The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins which terminate on the posterior surface of the liver in the inferior vena cava.

8. The *dorsalis pedis artery* is the continuation of the anterior tibial artery, and extends along the dorsum of the foot, from the anterior ligament of the ankle joint, midway between the two malleoli, as far as the first intermetatarsal space, where it divides into the dorsalis hallucis and the plantar or perforating. *Relations.—Superficial:* Skin, fascia, anterior annular ligament, and innermost tendon of extensor brevis digitorum. *Deep:* Astragalus, navicular, middle cuneiform, and their ligaments. *External:* Vena comes, anterior tibial nerve, extensor longus digitorum. *Internal:* Vena comes, extensor proprius hallucis.

9. *Coverings of the testicle, from without inward:* Scrotum (skin and dartos), intercolumnar fascia, cremasteric fascia, infundibuliform fascia, tunica vaginalis.

10. The *ovary* consists of a covering of *germinal epithelium, a stroma* and the *Graafian follicles*. The *germinal epithelium* is a layer of tall columnar cells on the surface. The *stroma* is a fibroelastic structure with many spindle-shaped cells and *interstitial cells*. Some of the latter are derived from the germinal epithelium, some are cells of luteal tissue. Near its attachment to the broad ligament there are numerous plain muscle fibers. The *Graafian follicles* are scattered throughout the stroma. They are small towards the surface, large towards the interior, but the ripest enlarge to such an extent as to reach the surface again. Each follicle is enclosed in an outer tunic of fibrous tissue of the stroma and an inner more cellular tunic.—(*Aids to Histology*.)

11. The *frontal sinuses* are two irregular shaped air cavities, situated between the two lamellæ of the vertical part of the frontal bone. They are separated by a thin septum; and each sinus has trabeculæ of bone. They are not present at birth, and occasionally do not develop at all. The right sinus is generally the larger. The floor is thin, and is over the orbit and upper part of the ethmoid. The sinuses are lined with mucous membrane, and communicate with the middle meatus of the nose by a duct called the infundibulum.

12. The *heart* is located obliquely in the thorax, between the lungs, and enclosed in the pericardium. A line from the lower border of the second left costal cartilage (one inch from sternum) to upper border of third right costal cartilage (half inch from sternum) represents the *base line;* the *right side* will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth left intercostal space three and one-half inches from mid-line); the *left side* from left end of upper border to left of apex. The heart lies opposite the fifth, sixth, seventh, and eighth dorsal vertebræ.

Its walls consist of muscle fibers, with some connective tissue to which many of the fibers are attached. The heart is divided by a septum into a left and right heart; and each side is further divided into an upper chamber (auricle) and a lower chamber (ventricle), connected with valves so arranged that circulation of the blood only occurs in one direction. In the *right auricle* are the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. In the right auricle are also found the openings of the superior and inferior venæ cavæ, coronary sinus, foramina of Thebesius, the auriculo-ventricular opening, the fossa ovalis, annulus ovalis, tubercle of Lower, and the musculi pectinati. In the *right ventricle* are the tricuspid and semilunar valves; also the columnæ carneæ, chordæ tendineæ, and the auriculo-ventricular opening and the opening of the pulmonary artery. In the *left ventricle* are the mitral and semilunar valves, the columnæ, chordæ tendineæ, and the aortic and auriculo-ventricular opening. The heart is about 5 x 2½ x 3½ inches, and weighs about ten ounces. It is supplied with blood by the right and left coronary arteries. The nerve supply is from the superficial and deep cardiac plexuses, and from the vagus and sympathetic system.

PHYSIOLOGY.

1. The *retina* is composed of several layers, from without inwards, as follows: (1) Layer of pigment cells; (2) layer of rods and cones; (3) the external limiting membrane; (4) the outer nuclear, or granular, layer; (5) the outer molecular, or reticular, layer; (6) the inner nuclear, or granular, layer; (7) the inner molecular, or reticular, layer; (8) the layer of ganglion cells; (9) the layer of nerve fibers; and (10) the internal limiting membrane. These structures are bound together by sustentacular fibers or neuroglia. The portion concerned in most acute vision is the macula lutea, and especially its central portion, the fovea. The *blind spot* is that part of the retina at which the optic nerve enters; it is occupied entirely by fibers of the optic nerve, and is devoid of any elements of the retina; it is insensitive to light. When the retina is suitably stimulated by light, there are produced sensations of light, of color, and of form.

"Of all the layers of the retina, the rods and cones appear to be the most essential to vision. It is only this layer that is capable of receiving the light stimulus and of transforming it into some specific form of energy, which in turn arouses in the fibers of the optic nerve the characteristic nerve impulses. A ray of light entering the eye passes entirely through the various layers of the retina, and is arrested only upon reaching the pigmentary epithelium in which the rods and cones are embedded. As to the manner in which the objective stimuli—light and color, so called—are transformed into nerve impulses, but little is known. It is probable that the ether vibrations are transformed into heat, which excites the rods and cones. These, acting

as highly specialized end-organs of the optic nerve, start the impulses on their way to the brain, where the seeing process takes place. As to the relative function of the rods and cones, it has been suggested, from the study of the facts of comparative anatomy, that the rods are impressed only by differences in the intensity of light, while the cones, in addition, are impressed by qualitative differences in color. The nerve-fibers themselves are insensible to the impact of the ether vibrations, and require for their excitation some intermediate form of energy."—(Brubaker's *Physiology.*)

2. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

3. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being (in males) about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. In females, the pressure is from 10 to 15 mm. lower. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure is estimated by a sphygmomanometer. *Arterial pressure* is produced and maintained by: the force and contraction of the left ventricle; the volume of blood pumped by the heart into the already full arteries; the action of the aortic semilunar valves in preventing regurgitation of the blood into the left ventricle when it goes into diastole; the elastic resiliency of the middle coats of the large arteries; the peripheral resistance exerted by the muscular wall of the arterioles, which are especially controlled by the vasomotor nerves; the increased surface over which the blood flows through the capillaries; and the tension of the extravascular tissues. The *capillary pressure* depends upon the condition of the arterioles. If the arterioles to a part dilate, the capillary pressure rises; if they constrict the capillary pressure fails. If, however, the venous pressure is raised, the capillary pressure must consequently rise too. Gravity very materially influences the capillary pressure. The *venous pressure* is influenced by: The presence of valves, which prevent a backward flow; and respiratory movements.—(From Lyle's *Physiology.*)

The *velocity of the blood flow* is largely influenced by the same factors as the blood pressure, particularly the force of the ventricular systole and the peripheral resistance. The possibilities of the variations in these factors are shown in the following table from Waller, in which the plus sign denotes an increase and the minus sign a decrease in effect:

HEART.	ARTERIOLES.	BLOOD-PRESSURE.	BLOOD-FLOW.
Force constant..	Resistance increased	+	—
Force constant..	Resistance diminished	—	+
Force increased .	Resistance constant	+	+
Force diminished	Resistance constant	—	—
Force increased .	Resistance diminished	+ —	+
Force diminished	Resistance increased	— +	— —
Force increased .	Resistance increased	+ +	+ —
Force diminished	Resistance diminished	— —	— —

4. *Contraction wave of the heart.*—"It seems to be demonstrated that normally the contraction of the heart begins in the sinus tissue of the right auricle, the so-called sino-auricular node or in the neighboring sinus tissue. The tissue of the sino-auricular node is designated sometimes as the pace-maker of the heart, on the assumption that its rhythm sets the pace for the rate of the beat of the whole heart. . . . In the mammalian heart, when exposed to view, it is evident that the auricular systole is not sufficient to empty its cavity, so far at least as the atrium is concerned. The contraction of the auricular appendages is more forcible. The contraction may be regarded as a rapid peristalsis, which sweeps a portion of the blood before it into the ventricle. . . . The systole of the ventricle is to the eye a simultaneous contraction of the whole musculature. Various observers, however, have shown that the wave of contraction travels over the heart with a certain velocity, which for the human heart has been estimated at 5 m. per second. It is probable that this wave starts at the base of the ventricle and travels along the course of the fibers—that is, first toward the apex and then into the interior of the heart. In regard to this point there have been great differences of opinion among different investigators. . . . Between the auricular and the ventricular contractions there is a perceptible interval which for the human heart can be estimated from a study of the records of the jugular pulse. The interval between the *a* and the *c* waves, the *a-c interval* as it is called, marks the time intervening between the contraction of the auricles and of the ventricles. This interval may be valued at 0.2 sec. or less, and is due chiefly to the time necessary for the excitation wave to pass over the conducting system between the auricles and ventricles. In all probability the conduction in this system is slower than in the musculature of the auricles or ventricles."—(Howell's *Physiology.*)

5. *Vasomoter regulation.*—"There are two antagonistic sets of nerve fibers: First, the vasoconstriction fibers, whose action causes a contraction of the muscular coats of the arteries, and therefore a diminution in the size of the vessels; second, the vasodilator nerve fibers, whose action causes an increase in size of the blood-vessels, due probably to a relaxation (inhibition) of the muscular coats of the arteries. . . . The main facts regarding the vasomotor apparatus may be summarized as follows:

Efferent vasomotor nerve fibers.
- I. Vasoconstrictor fibers—distributed mainly to the skin and the abdominal viscera (splanchnic area), all connected with a general center in the medulla oblongata, and in constant tonic activity.
- II. Vasodilator fibers—distributed especially to the erectile tissue, glands, bucco-facial region, and muscles; not connected with a general center and not in tonic activity.

Afferent fibers giving vasomotor reflexes.
- I. Pressor fibers. Cause vascular constriction and rise of arterial pressure from reflex stimulation of the vasoconstrictor center, *e.g.* sensory nerves of skin.
- II. Depressor fibers. Cause vascular dilatation and fall of arterial pressure from reflex inhibition of the tonic activity of the vasoconstrictor center, *e.g.* depressor nerve of heart.
- III. Depressor (or reflex vasodilator) fibers. Cause vascular dilatation and fall of arterial pressure from stimulation of the vasodilator center, *e.g.* erectile tissue, congestion of glands in functional activity.

It may be supposed that under normal conditions the activity of this mechanism is adjusted so as to control the blood-flow through the different organs in propor-

tion to their needs. When the blood-vessels of a given organ are constricted the flow through that organ is diminished, while that through the rest of the body is increased to a greater or less extent corresponding to the size of the area involved in the constriction. When the blood-vessels of a given organ are dilated the blood-flow through that organ is increased and that through the rest of the body diminished more or less. The adaptability of the vascular system is wonderfully complete, and is worked out mainly through the reflex activity of the nervous system exerted partly through the vasomotor fibers and partly through the regulatory nerves of the heart." (Howell's *Physiology.*)

6. *Intracranial pressure.*—"By intracranial pressure is meant the pressure in the space between the skull and the brain,—therefore the pressure in the subarachnoidal liquid and presumably also the pressure in the ventricles of the brain, since the two spaces are in communication. This pressure may be measured by boring a hole through the skull, dividing the dura, and connecting the underlying space with a manometer. Observers who have measured this pressure state that it is always the same as the venous pressure within the sinuses. This we can understand when we remember the close relations between the subarachnoidal liquid and the large veins and sinuses. We may consider that the large veins are surrounded by the cerebrospinal liquid, and consequently an equilibrium of pressure must be established between them; any rise in the intracranial pressure raises venous pressure by compression of the veins. This statement holds true at least so far as the intracranial pressure is due to the circulation. The intracranial pressure is caused and controlled normally by the pressure within the arteries and capillaries. This pressure, by enlarging these vessels, tends to expand the brain against the skull, and exercises a pressure, therefore, upon the intervening cerebrospinal liquid. This pressure, however, cannot exceed that in the veins, since, as said, an excess will be equalized by a corresponding compression of the veins. The venous pressure in the end determines, therefore, the actual amount of intracranial pressure. Conditions which alter the pressure in the cerebral veins affect the intracranial pressure correspondingly. Thus, compression of the veins of the neck raises the pressure in the cerebral veins and also intracranial pressure, and a higher general arterial pressure also results finally in a higher pressure in the cerebral veins and therefore in the subarachnoidal space. Under pathological conditions, such as tumors, abscesses, excessive formation of cerebrospinal liquid, etc., which lead to a general compression of the brain, intracranial pressure may be increased beyond normal limits. Experimental investigations show that so long as the intracranial pressure remains below that of the arteries supplying the brain the circulation through the brain is not markedly affected. If, however, the intracranial pressure rises above general arterial pressure the flow through the substance of the brain is prevented and a condition of anemia results which would presumably cause unconsciousness. In anesthetized animals submitted to such a condition it has been shown that a compensation takes place; the anemic condition of the medulla stimulates the cardio-inhibitory center, causing a slower heart-beat; at the same time it stimulates also the vasomotor center, causing a general vasoconstriction in the rest of the body, the result of which is to raise the arterial pressure and reestablish the cranial circulation (Cushing)."—(Howell's *Physiology.*)

7. *Intrathoracic pressure* is "the pressure in the pleural cavity and mediastinal spaces. This pressure, under normal conditions, is always negative,—that is, is always less than one atmosphere. The reason for this is simply that the lungs are distended to fill the thoracic cavity, and consequently the organs, like the heart, which lie in this cavity outside the lungs, are exposed to a pressure of one atmosphere, minus the force of elastic recoil of the lungs. The heart and other intrathoracic organs are protected from the direct pressure of the air by the thoracic walls; they are pressed upon, however, through the lungs, but naturally the atmospheric pressure is reduced by an amount equal to the elastic force of the distended lungs. Intrathoracic pressure, in fact, may be defined as intrapulmonic pressure minus the elastic pull of the lungs, and since under usual conditions the intrapulmonic pressure is equal to that of the atmosphere, the intrathoracic pressure is less than an atmosphere by an amount equal to the recoil of the lungs. The negative pressure in the thorax is, therefore, equal to the elastic force of the lungs, and is larger the more the lungs are put upon the stretch,—that is, the deeper the inspiration." (Howell's *Physiology.*)

8. *Respiratory reflexes.*—"The mucous membrane of the larynx receives its sensory fibers from the superior laryngeal nerve. When this nerve is stimulated artificially the respirations are always inhibited; the chest comes to rest in the position of passive expiration. The same effect may be obtained from the sensory fibers of the glossopharyngeal supplying the pharynx, and indeed a temporary inhibition of respirations occurs through this nerve during every act of swallowing. The sensory fibers of the nasal mucous membrane (trigeminal) cause a similar reflex inhibition when stimulated by injurious or so-called irrespirable gases, such as HCl, Cl, NH_3, SO_2, etc. We may regard this inhibitory influence exerted by the sensory fibers distributed along the air passages as a protective reflex which guards the lungs automatically from injurious gases. This protective action is made more evident by the fact that, together with the cessation of respirations, the glottis is reflexly closed by contraction of the adductor muscles and, if the stimulation is strong, even the bronchial musculature may be contracted, so that in every way the passage to the alveoli is made more difficult. The reflex is, of course, more or less temporary but it possesses the great advantage of being automatic and may enable the animal or individual to escape unharmed from a dangerous locality before the increasing irritability of the respiratory center breaks through the inhibition. . . . We know also that irritating gases or foreign bodies of any sort that enter the larynx may lead to a coughing reflex,—that is, to a series of expiratory blasts which have a purposeful end in the expulsion of the stimulating object. In this case there is not simply an inhibition of the inspiratory movements, but a reflex excitation of a peculiar type of expiratory movements." (Howell's *Physiology.*)

9. *Cardiac cycle.*—"We may begin with the closure of the semilunar valves. At that moment the second heart sound is heard and at that moment the ventricle is quickly relaxing from its previous contraction. Since the auriculoventricular valves are still closed, the ventricles for a brief interval are shut off on both sides. The blood is flowing steadily into the auricles and dilating them. As soon as the ventricles relax, the pressure of blood in the auricles opens the auriculoventricular valves, and from that moment until the beginning of the auricular systole the blood from the large veins is filling both ventricles and auricles. The venous blood which has been accumulating in the auricles during the ventricular systole flows into the ventricles with some suddenness on the opening of the auriculoventricular valves. The ventricles, therefore, dilate rapidly and the auriculoventricular valves are floated into a position ready for closure. . . . The auricular systole sends a sudden wave of blood into the ventricles, dilating them still further and momentarily blocking or retarding the flow from the large veins. The ventricular systole follows at once upon the auricular systole. As the ventricle enters into contraction the auriculoventricular valves are tightly closed, the first sound is heard, and for a short interval the ventricular cavity is again shut off on both sides. Soon the rising pressure in the interior forces open the semilunar valves, and then a column of blood is discharged into the aorta and pulmonary artery as long as the contraction lasts. During this interval the flow at the venous end of the heart continues, the blood being received into the yielding auricles. . . . At the end of the ventricular systole the excess of pressure in the aorta and the pulmonary artery closes the semilunar valves and completes the cycle."—(Howell's *Physiology.*)

10. One part of raw animal food to three parts of raw vegetable foods is about the proper proportion.

11. *Myenteric reflex, or law of the intestine.*—"The peristaltic movement consists in a constriction of the

walls of the intestine, which, beginning at a certain point, passes downward away from the stomach, from segment to segment, while the parts behind the advancing zone of constriction gradually relax. The wave of constriction may be recorded by the use of suitable apparatus. When thus recorded it is found that the advancing area of constriction is preceded by an area of inhibition or relaxation, so that the peristaltic movement consists of two parts, following in a definite sequence, which seem to combine to facilitate the movement onward of the intestinal contents; for it is obvious that the wave of constriction will be more effective in forcing the contents forward if just in front of it the intestine is relaxed by inhibition of the tonicity of the muscular coat. Bayliss and Starling, to whom we owe the discovery of this two-fold character of the movement, regard it as a reflex which is controlled within the intestinal wall itself through its intrinsic ganglia and their afferent and efferent connections. When a bolus is inserted into the intestine at any point its effect upon the sensory fibers is such as to cause a reflex contraction of the muscle above the bolus, that is, toward the stomach, and a reflex inhibition or dilatation below. They speak of this definite relationship as the *law of the intestine;* it is described also under the name *myenteric reflex.* It is obvious that the circular layer of muscles is chiefly involved in peristalsis, since constriction can only be produced by contraction of this layer. To what extent the longitudinal muscles enter into the movement is not definitely determined." (Howell's *Physiology.*)

12. *Nervous mechanism of vomiting.* — Normally, vomiting is a reflex act. "The *afferent* nerves are principally the fifth, and glossopharyngeal (as in vomiting produced by tickling the fauces), and the vagus (as in vomiting produced by gastric irritants); but vomiting may occur from stimulation of other sensory nerves, *e.g.* those from the kidney, uterus, testicle, etc. The medullary centers may also be stimulated by impressions from the cerebrum and cerebellum, producing so-called *central* vomiting occurring in diseases of those parts. The *efferent* (motor) impulses are carried by the vagi to the stomach, by the phrenics to the diaphragm, and by various other spinal nerves to the abdominal muscles. It is very doubtful whether there is any separate center for vomiting; the center for the reflex coincides with those of the nerves mentioned in the medulla oblongata. *Emetics.*—Some emetics produce vomiting by irritating the stomach; others, such as tartar emetic, apomorphine, etc., by stimulating the medullary centers." (Halliburton's *Physiology.*)

MATERIA MEDICA, THERAPEUTICS, PHARMACOLOGY, AND PRESCRIPTION WRITING.

1. By *incompatibility* is understood the simultaneous administration or combination of substances not suitable for such combination. *Therapeutic incompatibility* occurs when two agents are administered together which have antagonistic physiological actions, such as morphine and atropine; this is often intentional. *Chemical incompatibility* occurs when remedies which are mixed together undergo chemical decomposition or explosion. *Pharmaceutic incompatibility* is seen in compounding a resinous tincture with an aqueous solution.

2. *Treatment of Spanish Influenza.* — The patient should be ordered to remain in bed, and be kept warm; he should be isolated as much as possible. Some stimulant such as aromatic spirit of ammonia may be given in 30 minim doses in water every 3 or 4 hours. The following prescription will prove useful:

℞ Extracti aconiti.....gr. ijss
Acetphenetidini 3j
Quininæ sulphatis.....gr. xxiv
Pulveris Doveri .....gr. xij
Misce et. in caps., No. xxiv.
Signa: Take two every three hours.

The patient should have plenty of water to drink, and liquid food; fresh air is necessary. A tonic will be required when convalescence sets in.

3. Digitalis is indicated in diseases of the heart: (1) when heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; 3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc.

4. *"Pituitary extract,* containing the principle found in the posterior lobe which acts on unstriped muscle, is now an ordinary article of commerce for many therapeutic purposes. It is a favorite remedy for surgical and toxemic shock, and many observers are convinced that it does good by raising the blood-pressure. A very valuable effect is that it promotes peristalsis even when purgatives fail or are vomited, as in cases of intestinal paralysis after abdominal operations. A third indication is to increase labor pains; sometimes in cases of weak pains the child is expelled very rapidly after an injection. It is a powerful diuretic. As a galactagogue its success so far has been doubtful. Feeding with the gland may be valuable in some forms of amenorrhea. Pituitary extract must not be given frequently at short intervals, or its effect may be reversed."—(Short's *Newer Physiology.*)

In obstetrics, pituitrin should not be given until the cervix is dilated or dilatable, and it should be remembered that sometimes the contractions produced by it are so energetic as to endanger asphyxiation of the child and rupture of the uterus.

5. SALICYLIC ACID. *Origin.*—It is derived from oil of wintergreen; also made synthetically by combination of sodium carbonate and carbon dioxide; this is then treated with hydrochloric acid. *Physiological action.*—"Antiseptic; irritant; strongly cholagogue; antipyretic, diaphoretic; diuretic (markedly increasing the excretion of uric acid). In exceptional instances skin eruptions are caused, and in some individuals a train of symptoms analogous to those of cinchonism, and designated as *salicysm,* results from the use of salicylic preparations." *Dose.*—Twelve grains.

6. *Adrenalin is used in solutions of novocaine for local anesthesia:* (1) To prolong the anesthesia; this is accomplished by the vasoconstrictor action of the adrenalin on the local vessels, and this prevents the rapid removal of the anesthetic by the blood stream. (2) To prevent local hemorrhage; this is also accomplished by the vasoconstrictor action of the adrenalin.

7. OXYGEN. *Physiological effects:* "The inhalation of oxygen causes a sensation of warmth in the respiratory passages and increases the appetite and the mental and bodily vigor. The red blood corpuscles are increased in number and stimulated to greater activity. *Therapeutic uses:* Cardiac disease, pneumonia, pulmonary edema, emphysema, convulsions, chloroform narcosis, asphyxia from toxic gases, and in various other conditions characterized by great lividity or by dyspnea due to causes interfering with the oxygenation of the blood; also in chronic conditions such as anemia, albuminuria, glycosuria, and phthisis." *Mode of administration.*—The oxygen is under compression, and is contained in steel cylinders. It is passed through water in a bottle and conveyed through a rubber tube terminating in a funnel which is held in front of the patient.

8. *Drugs which are excreted in the milk.*—Rhubarb, senna, scammony, castor oil, opium, arsenic, iron, lead, mercury, salts, and potassium iodide.

Substances which increase the flow of milk.—Tonics, good food, pilocarpus, and leaves of the castor oil plant applied locally.

Substances which decrease the secretion of milk.—Belladonna, antipyrine, potassium iodide, colchicum with magnesium sulphate, compression of the breasts, camphor applied locally, and bandaging the breasts with adhesive plaster or belladonna plaster.

9. *Dichloramine-T* is a new chlorine compound containing twice as much chlorine as chloramine-T, and having a more powerful germicidal action. It is generally used in a five per cent. solution, and is applied by means of an oil spray. The solution should be freshly prepared, and applied to the wound once a day. The wound is cleansed and dried, and all devitalized tissues are to be removed, bleeding vessels must be ligated, and the wound surfaces then sprayed with the

solution. Drainage may be necessary; and antiseptic dressings are applied. It acts as a disinfectant; and under its influence wounds heal rapidly. No Carrel tubes are needed; the wound has only to be dressed once a day, and so the patient is saved pain and discomfort; there is also a saving of time for doctors and nurses, and also a saving of material used in dressing the wound.

10. *Treatment of acute rheumatism.*—"The patient must be kept absolutely at rest in bed. He should lie between blankets, not sheets, and should wear a flannel night-gown. The diet should consist of milk, diluted with mineral water; if it does not agree, chicken broth may be given. In convalescence it may be more ample, but red meat should be sparingly used. Salicylate of soda, or salicin, is the specific remedy, the latter being the less depressant form. In severe cases, the salicylate should be given in doses of gr. xx every two hours until the pain is relieved, thereafter every four hours till the temperature falls, and then less frequently and in smaller doses, its withdrawal being gradually accomplished. In less severe attacks gr. xx every four hours may suffice. Should the salicylate disagree, other salicyl compounds (oil of wintergreen, aspirin) may be used. In the view of the majority, the salicylates shorten the course, protect the heart, and lessen the liability to relapse; but some still prefer the alkaline treatment, in which case large doses (℥iss) of sodium bicarbonate are given every three hours. The amount is lessened when the urine becomes alkaline. If the pain in the joints is severe, they should be fomented, and the limb should be put upon a splint. A lotion of carbonate of soda and laudanum, or a liniment of methyl salicylate may give relief; and morphine is sometimes required at first. Hyperpyrexia should be treated by the cold bath."—(Wheeler and Jack's *Handbook.*)

For acute rheumatism:

℞ Sodii salicylatis.....℥iv
Potassii bicarbonatis.....℥iv
Aquæ menthæ piperitæ, q. s., ad.....℥iv
Misce et signa: One dessertspoonful, in water, after each meal.

11. *Non-operative treatment of acute cholecystitis:* The line of treatment to be adopted depends entirely on the cause of the catarrhal inflammation. If it arises from cold and exposure and is seen early a warm bath or a vapor bath, and the use of saline cathartics, or of small doses of tartar emetic, are of service. Full doses of quinine and Dover's powder at bedtime, with a light purge in the morning, will often relieve the general symptoms of "cold," and exert a favorable influence upon the local catarrh. If the cause of the disease is a coexisting gastroduodenal catarrh, a mechanical emetic, repeated twice on each of the first two days, is often of service. Large draughts of hot water, either at bedtime or repeated throughout the day, are grateful and beneficial. They are made more palatable by the addition of some one of the alkaline citrates. At the same time an alkaline purgative, largely diluted, should be employed, and then gastric sedatives or the mineral acids. . . . A mercurial purgative is first administered; from one-twelfth to one-third of a grain of calomel, in combination with from three to ten grains of bicarbonate of soda every two hours, until eight or twelve powders are taken. If the bowels are not acted on freely by this combination, it should be followed by a saline laxative. At the same time light sinapisms are applied to the epigastrium. . . . Alkaline effervescing waters, as the Carlsbad, Vichy, or Hathorn waters, or the salts of ammonium, sodium, or potassium may be used. Bartholow advocates the phosphate of sodium in drachm doses. The muriate of ammonium is one of the most reliable alkalies; it may be given in ten or twenty grain doses, three or four times daily, combined with an equal quantity of powdered licorice, and dissolved in water. Ipecacuanha has been advocated in small doses, as one-half of a grain or one grain, frequently repeated, for the same purpose. To increase the secretion, nitrohydrochloric acid, the vegetable hepatic stimulants, benzoate and salicylate of soda, and alkaline waters are of service. The alkalies should be taken in a large amount of water, preferably hot, on an empty stomach, and by slowly sipping the fluid. Emetics are also used for their mechanical effect, but care must be observed lest their too free use incite a fresh catarrh or aggravate the one already existing.—(From *Reference Handbook.*)

12. *Psychotherapy:* "For ordinary therapeutic purposes, the physician may be content to know only the physical signs and symptoms of his patient's affection. For psychotherapeutics, he must, if he would be successful, know every possible source of worry and annoyance and, as nearly as may be ascertained, every slight phase of physical fatigue that may be a disturbing factor in his patient's life. It is surprising how many things the physician will find to correct when he carefully goes over all the actions of the day and ascertains all the possible sources of worry and anxiety his patient may have. It may happen that in many cases he will be unable immediately to remove these sources of worry. But there is relief in telling them, and then, even when they cannot be completely eradicated, they can often be modified. Every improvement of this kind, however slight, is a fountain of favorable suggestion which makes the patient look on the brighter side of life. From every amelioration, however trivial, there is a reaction on the feelings that gives more and more confidence. . . . Psychotherapy represents one of the important elements in therapeutics, and we must learn to use it in a way suitable to our patients. We have to learn to use our drugs in accordance with the nature and physical make-up of the patient. We have to find out by experience just how to use hydrotherapy for each individual. Varying currents of electricity and varying forms of electrical action are needed for different individuals. Just in the same way, our psychotherapy must be dosed out according to the special need of each individual, the form of the affection and the particular kind of mind that is to be dealt with. To learn the place of mental influence in healing, so that we shall not be attributing to other therapeutic factors what is really due to the mind, will be a great advance in therapeutics. In brief, the applications of the general principles of psychotherapy include all means, apart from the physical, of influencing patients. Drugs will always have a large place in rational therapy. Many physical remedial measures, hydrotherapy, electrotherapy, climatotherapy and others, must be important adjuncts. To these is now added psychotherapy. It has been used before, as have most of the other forms of therapy, but in our day we are trying to systematize therapeutic modes so as to secure the greatest possible information with regard to their exact application. This is what must be done with regard to psychotherapy also. Just now its importance is being exaggerated by ardent enthusiasts. The business of the practicing physician must be to select what is best, and above all what is sure and harmless, from the many suggestions offered, so as to build up a practical body of applied truth."—(Walsh's *Psychotherapy.*)

THE ROLE OF CELL NECROSIS AND BACTERIAL INVASION IN SURGERY.*

By FENTON B. TURCK, M.D.,

NEW YORK.

ACCORDING to recent reports of the Allied Medical and Surgical Congress the failure to cure shock, wound diseases, and pneumonia is an admitted fact. The defeat of old theories of healing is as complete and humiliating as the defeat of the German Navy. Men like Bayliss,[1] Gray,[2] Bowlby,[3] Wright,[4] Archibald McLean,[5] Sweet,[6] Goodby,[7] Charles,[8] Crile,[9] and Cannon among the British and Americans were admittedly forced by the facts of their experience to a "change of ideas."†

Among the French many authorities like Quenu,[10] Bertein and Ninier,[11] Soubeyan,[12] Brechot and Claret[13] agree in this change. The withering storm of war forced upon them all the conclusion so well expressed by A. J. Hull,[14] who says: "In spite of the advances in surgery, our wound and shock treatment is no more efficacious than in the days of the Trojan War."

Soubeyan's[15] experiences bear out this conclusion. Among 445 wounded, he states that there were 145 deaths, 93 of which were due to shock. All the inoperable cases died, and of the operable cases only five recovered. "We *had* to change our ideas," says Speed.

The disheartening thing about this statement is that in changing their ideas the surgeons turned backward instead of going forward; they returned to the methods of Larry[16]—the methods of the Napoleonic Wars—"débridement" became the common practice, and while it undoubtedly saved many who otherwise would have perished, it was after all a reversal and not an advance.‡

The treatment of pneumonia, which often follows the wounds, seems to have been left *precisely where it was.* Pneumonia still remains the most terrible scourge of our cantonments.[17] Reports show that the mortality from this disease runs from 41.8 to 89.6, a condition too appalling to permit of any apology. It is a challenge to the entire medical profession.

The Public Health Association reports (Dec. 9-12, 1918)[18] that during the months of September, October, and November 400,000 deaths from pneumonia occurred in the United States alone, and that the microorganism (or virus) responsible for these deaths remains unidentified.*

Colonel Vaughan[19] states the case plainly: "So far as respiratory diseases are concerned we know no more than our ancestors knew one hundred years ago, and we may as well admit it. I say that in the face of the greatest pestilence that ever swept our country, we are just as ignorant as the Florentines were in the plagues described in history."

Resumé of the Writer's Previous Work.—Now in opposition to these startling and disheartening statements concerning the treatment of shock, wound disease, and pneumonia, I beg leave to place before you the results of nearly thirty years of laboratory investigation concerning these diseases. I am confident that we are going forward and that it is possible not only to cure a large percentage of wounded men, but to check the scourge of pneumonia.

Let me begin by stating in the plainest possible way that my work, experimental and clinical, has led me to the conclusion that shock and all other manifestations arising from wounds, as well as other secondary conditions such as ulcer or pneumonia, are produced by the absorption of a poison which is a product of necrosed and disintegrated cellular tissue. In other words, I have found that man's greatest enemy is his own decaying tissue. I have demonstrated that these destructive agents

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, January 3, 1919.

†Cannon, in a paper on "Traumatic Shock," recently read before the Société de Biologie, Paris (*Jour. A. M. A.*, December 28, 1918), reaches the conclusion that apparently the victims of shock are poisoned with toxins which may cause death either by rapid action on the nervous system or by acting on the liver and other organs. Professor Delbet in discussing this paper says: "This meeting will be historic in that it is the first time that biologists, physiologists, internists, and surgeons have met together and agreed almost unanimously on the toxic origin of shock."

‡Larry says: "The effects of commotion ('shock'), far from being aggravated, diminish and disappear insensibly after the operation." Larry's method of débridement obviously resulted from the French surgeon's observations and experience in the American Revolution. Duboys, who served with the French troops in American during the War of the Revolution, states that "American surgeons amputated at once (primary operation) and lost but few, but the French delayed and lost many." This is evidently one of the many original ideas that were developed under Benjamin Rush, the surgeon-general of our armies during the Revolution. We now understand the reason why these operations were so successful. It was because the shock (commotion) could not develop because the disintegrating tissues that cause shock (traumatic shock) were removed.[16]

*Nuzum, Pilot, Stangl, and Bonar[23] state that lung puncture in a large number of cases showed that the lung was sterile. In post-mortems pneumococci and streptococci were found, but they appeared to be *secondary* invaders. The influenza bacillus was isolated in only 8.7 per cent. of the cases.

called polypeptids are the death-dealing forces which act in pneumonia as well as in cases of wound and shock.

Furthermore, I have proven that not only are these products of necrosed tissue the cause of death in wounds and pneumonia, and the factors of such diseases as neuritis and various forms of rheumatism, but that they are the chief means of transmitting disease from man to man. Bacteria merely assist in the process. It is wasted energy to conceive that the poison of the cells is psychogenetic, or that it is the direct result of a foreign body called a germ.

It is true that where necrosis occurs from any injury germs are afforded a chance to grow,[40, 50] and by their catalytic action they undoubtedly speed the progress of disintegration, but they do not furnish the poison. The high viscosity and coagulation of the blood and body fluids which cause sickness and death are due not to germs but to the poisonous products arising from decaying cells.

The reason for the humiliating failure of surgery in this war lies in the fact that laboratory workers in research experimentation were too remote from the empirical and clinical happenings of the field, and that physicians and surgeons in war hospitals were not in a position to reproduce in animals the pathological conditions they found on the field and in the clinics. It was for these reasons that they fell back on traditional theories and practices instead of making the advances which were expected of them.

In all my research work clinical observations have been carefully checked up by means of laboratory experimentation. For twenty-five years I have continued, almost daily, to work in my laboratory and to make immediate and careful comparison between that work and my clinical experience. The value of my conclusions depends entirely upon that method.

My early conception of the fact that the necrosed cellular tissue furnished the most destructive of man's diseases came from the treatment of a patient in 1893 suffering from the effects of alcohol.[34] The use of alcohol had been discontinued for some months and the alcohol had all passed out of the system, and still the necrosis and the effect of the poison of the necrosed cells persisted. Careful investigation led me to the conclusion that no effect of the protein poison took place until it reached the cells in the capillary area. I observed that the cells responded at once to the poison.[35, 43] Coagulation of the tissue fluids took place and this increased viscosity of the blood was passed on to the veins. Later I demonstrated that where this coagulative phenomenon occurred suddenly death was instantaneous.[61, 62] If the process went on more slowly a chronic condition resulted.[38, 63]

In subjecting this conception to experimental test I treated the stomach mucosa of animals with reagents which caused immediate death of the tissue. In these experiments the different agents used to produce cell necrosis included acetic acid, tannic acid, chromic acid, silver nitrate, and mustard oil (in large and small doses administered for months), chloroform, and ether. The result in all instances was a breaking down of the cells and a change in the splanchnic circulation as a result of the absorption of the toxic products from the cell necrosis. In this condition of the tissues, if bacteria were introduced they more readily migrated and caused a further disintegration of the cells.[38, 40, 45, 50] In these experiments I was able to cause gastritis. Small doses acted like a stimulant, large doses caused cellular decay. Where the necrosis was small in amount the resulting agents stimulated; if it was extensive, they caused disease and death.

This conception was then put to further test by means of direct observation of the mouth, nose, throat, and stomach.[39] I demonstrated that only when the necrosis of the cells was well established was it possible to grow germs on the wall or between the gland cells. Examination from time to time showed that the bacteria at no time entered the tissue or blood current. The growth of the germs merely increased the necrosis of the cell. The germ did not make the poison directly; it only aided by its presence and growth the decay of the cell, thus adding to the amount but not changing the character of the poison.[40, 46]

By means of an instrument called the gyromele[40, 41] and by the use of nippers* I secured a specimen of the stomach wall and sections of the small intestines, by means of which I was able to study the progress of the disease on the internal organs. By these methods I proved that ulcers of the stomach were caused by cytolysis and autolysis, processes which in some cases resulted in perforation and death.[36, 46, 61, 66]

In these experiments, together with many others, I proved that it made no difference how the death of the cell was caused, the products of disintegration upon being absorbed produced autolysis, which when occurring in an area rich in ferments (such as the pyloric end of the stomach and duodenum) caused ulcers to form which ultimately perforated the muscle coat of the organ. Other diseases, such as dilatation of the stomach and intestines, were found to be due to a similar toxic influence, not on the nerves but on the *muscle cells* of the stomach and intestines.[57, 58, 69]

Experimental tests also revealed the fact that wound shock was due to a toxin produced by disintegrated animal tissue. I was able to produce the same effect by exposing the viscera to the air and afterward injecting the products of the resulting dead cells of the abdominal and pleural cavity into the animal.[68] The injection of such products caused

*Examination of the dead cells and bacteria was made possible by the invention, in 1893, of an instrument named the "gyromele," or revolving sound, and the "nippers," by means of which specimens of the stomach wall and small intestines could be secured at will in both experimental animals and patients for comparative study. This instrument is a very flexible cable, tipped with a soft sterilized sponge or *swab* placed within a long rubber tube, which could be passed through the stomach and through the pylorus into the duodenum. A small revolving attachment, not unlike a surgical drill, and palpation of the outer abdominal wall, or observation with the *x*-ray, by which the instrument may be directed to the area desired. This method of sounding the intestine has been used by the author ever since its invention. A special instrument was devised for the nose and throat on the same principle.[39] The Rockefeller Institute has adopted this principle for taking cultures. In 1903 emulsions of gastric membrane injected into five animals resulted in all showing necrosis and destruction of gland tissue.[57]

death from shock. Precisely similar results were obtained where the disintegration of the cells was the result of chloroform.[43]

Comparisons between experiments on animals and cases in the hospitals and clinics gave parallel findings.[44, 50] As I studied the clinical conditions side by side with the records of my years of experimental research work, I not only recognized the same phenomena, but determined upon a course of treatment in harmony with the facts. The leadings were clear and decisive. The right treatment was that which would neutralize the poison from the disintegrating cells and stop the process of necrosis. This treatment has been my practice for many years.[66, 67, 68, 69]

The great war which is now closing has brought us face to face with the appalling realization that a great malfeasance has been committed on those of our brave soldiers who were wounded in battle and exposed to the elements. We are confronted with the question, "Are *psychoneuroses* in shock and *germs* in wounds (and in cases of pneumonia) the *only* causes of these diseases?"

Bowlby says[3] it was really a race against time. With the awful tissue destruction in battle wounds autolysis or self-destruction of tissue cells begins the moment the local circulation is destroyed. The shock toxin thus formed is increased by the growth of bacteria. "The transmutation of war is swift" and débridement with primary suture became the exclusive preventive and curative measure against shock and "wound disease." At one stroke it removed the disintegrating tissue that caused the disappearance of shock, the wound disease, and all the train of symptoms.

In order to answer this question for myself and for others, I returned to my laboratory with renewed energy that I might extend my experiments to something like the actual conditions found in battle.[51, 52]

As a result of this recent investigation I have verified all previous experiments and conclusions, and now have an antitoxin (Serum "A") and certain autovaccine methods which prevent shock, or stop it if it has already occurred. By injecting an emulsion of human tissue into a horse I have been able to produce a wound-infection antitoxin. To increase the value of the antigen the human tissue was subjected to the hastening action of bacterial cultures and the resulting serum has been tested and found to be of the highest value in practice. It causes the rapid healing of all types of wounds.

So in pneumonia, an antitoxin "C," formed by the use of lung tissue, appears to have a specific value of the highest importance in the treatment of respiratory diseases. It has proven effective even in asthma and similar anaphylactic conditions.

Conditions Rather than Diseases to be Treated.—It is customary to classify the various injuries which affect the body under the heads "Mechanical," "Physical," or "Chemical," but in the last analysis all injuries register in the same area and in the same way. My experiments have shown that no effect of a blow is apparent until the force of the impact reaches the visceral area. Violent impact results in abrupt change in the visceral circulation, while a series of light percussions on the body surface is followed by a similar but more gradual stasis of the venules of the liver, lungs, stomach, and intestines. Shaking the animal, or discharging a shell in the air or in water in close proximity to it, produced identical symptoms. No matter what the injury might be the results were the same, differing only in degree.

Furthermore, fresh resected portions of the viscera such as loops of the intestines or pieces of the voluntary muscle tissue, when subjected to the same shock impulse, displayed the same coagulation of the tissue fluids and blood. Similarly, muscle tissue rendered liquid after freezinz, fresh blood drawn into a paraffined syringe, liquid gelatin, eggs, milk, and other colloidal substances when put in a "shock box" and subjected to the shell explosion promptly clotted or coagulated precisely as in the case of the live animal's tissue.[51, 52]

My experiments also show that no effect from cell necrosis was apparent until the polypeptids that resulted reached the visceral area, producing the identical condition of the colloids as occurred in impacts or mechanical blows. Precisely the same congestion or stoppage of the blood current in the viscera, *e.g.* stomach, intestines, liver, and lungs, occurred when there was disintegration of the body tissues resulting from mechanical or chemical injury.[35, 45, 51]

This disintegration always resulted in the formation of polypeptids. These polypeptids are specific to the species in which the action takes place, namely, cat tissue is poisonous to the cat more than to the dog, the tissue of the guinea-pig to the guinea-pig more than to any other animal, etc., though it is possible by the use of overwhelming doses and by sensitization to render an animal susceptible to an alien protein. On the other hand, we may regard each species already anaphylactic or sensitized to its own disintegrated tissue cells—polypeptids.

Wound injury may be produced by chemical means such as chloroform, because chloroform causes cell necrosis. Other agents will produce the same cell necrosis, such as burns, cauterization by chemical means; in fact, any agency which leads to cell disintegration will produce identical polypeptid products.

In my experiments many hundreds of animals, ranging in size from amebas to the horse, including mice, rats, guinea-pigs, cats, dogs, monkeys, sheep, goats, pigs, and horses, were used, and no matter what the species of animal might be and no matter what the character of the injury, whether mechanical, physical or chemical, the result was the same—*cell necrosis.* Microorganisms only increased the rate of cell digestion.[35, 46, 51, 66]

It will thus be seen that as disease phenomena occur primarily and principally in the tissue cellular area the coagulation extends from the tissue fluids to the contents of the capillaries, it lies outside of the vasomotor control. (Figs. 2 and 11.) The same may be said of "shock" which is produced in animals in portions of tissues removed from the body and in test tubes of blood. In short, all the facts indicate that the primary phenomena of shock are outside the domain of the nervous system.[43, 44, 51, 52]

With regard to the germ and the theory of its

action in disease and the transmission of disease (except as secondary invaders) all the facts of my experience are in opposition to the present teaching. The ancient belief that the sick man was possessed with a demon which must be driven out has its modern parallel in the belief that the starting point of disease is in the introduction of a foreign agent into the body.

The germ is the modern demon. You have but to substitute the idea of the germ for the idea of the demon and the medical practice of to-day is but a kind of exorcism. Time-honored traditions have a tenacious life and in this case we have a superstition surviving long after the attempt has been made to make medical treatment a science.

That psychoneurosis is the cause of wound shock and that disease can be cured by driving out or destroying a germ are errors arising out of theory rather than from experiment. Methods of treatment founded on these errors have collapsed in the face of the tremendous mortality from shock and wounds, and from pneumonia.

As Lloyd George has said, "The whole world must be remade," and in this reconstruction, medical and surgical practice must *also* be reformed.

(My experiments, with methods and results obtained, are placed at the end of this article. These confirm my previous clinical and experimental observations.)

Pathology.—The general pathology of the condition following absorption of the products of native cell necrosis (iso-autolysis) may be simply summarized in the general pathology of "peptone shock," as expressed many years ago by the writer:" "That we cannot apparently experimentally produce profound shock without the occurrence of *congestion* and that the reduction of such shock does not occur until we reduce the congestion and distribute the blood over the surface" (p. 1163).

Mechanical, physical, or chemical injury results in cell necrosis and autolysis. The absorption by the organism of these products results in the pathological conditions we have described. The symptom complex varies and is determined by the physiological factors involved.

Animals in "shock," with or without the addition of bacteria, all *show* the one fundamental primary change—a stoppage or stasis of the blood current originating in the capillary area of the visceral organs, the stomach, intestines, liver, and lungs. This stasis occurs in the venules and backs down into the larger veins in the portal zone of the liver, pulmonary and arterial zone (venous) of the lung, and submucous zone of the stomach and intestines. In abrupt sudden shock complete coagulation and instant death occur, while in *delayed* shock (subacute and chronic forms) the increased blood viscosity produces the same congestion or blood stasis. This is well shown in Figs. 1, 2, 3, 6, and 8 showing the lung, liver, stomach and intestine. The finer changes taking place appear to originate in contact with the tissue cells with the result that the surface tension produces adsorption of the colloids, the protoplasm of the cells, tissue fluids, and capillary blood. Sections cut from the organs during the progress of shock and microscopically examined in the fresh state indicate that the primary changes are apparently an *adsorption phenomenon* compared with normal tissue.

Section of the liver (Fig. 1) shows not only clotting in the capillaries, but demonstrates that the primary changes occur in the protoplasm of the cells. This coagulation phenomena occurs also in the fluids surrounding the cells and extends into the capillaries and larger veins. (Figs. 2 and 11.)

The lungs show identically the same phenomena and in analogous areas, *e.g.* in the pulmonary arterial zone. (Figs. 3 and 4.)

Sections of the stomach, intestine, liver, and lung, *in vivo* and post mortem, showed that the coagulation phenomena began at the cells and capillaries, and the clotting was seen in the large veins, *e.g.* submucous zone of the stomach and in the intestine —"*zona transformans*," the portal and periportal zones of the liver, and the pulmonary arterial zone of the lungs, this viscus often giving the pathological picture of pneumonia. (Compare Figs. 3, 4 and 7 with 9 and 10.)

The elective or preferential adsorption phenomenon is determined by the organ or tissues, though not absolutely specific.*

The first to show the colloidal character of living tissue and the energy we call surface tension that causes these reactions to occur was Thomas Graham,[25] who said, in 1861, "It may be looked upon as the probable primary source of force appearing in the phenomena of vitality," Jacques Loeb[26] and Pauli[27] anticipated that these ionized and non-ionized proteins would explain the mysteries of many life phenomena. The work of Jacques Loeb[24] on the influence of electrolytes on the precipitation of colloids like gelatin is far reaching in its future application to biology. We may look upon the coagulation of blood and plasma as an interaction between certain colloidal systems "under the influence of electrolytes" (Hardy's rule). "The intervention of surface action is shown by the accelerating effects of rough surfaces and the action of lipoids."[29]

*Thus muscle injected into the animal will produce reactions akin to pneumonia, but classical pneumonia more or less confined to the lungs is produced by the insufflation of lung tissue (cat). (See Figs. 4, 5.) We found this specific character true also when applied to the alimentary tract in the production of gastric ulcer.[57, 46, 61, 66] J. L. Whitney[32a] concludes that in all fatal cases of nephritis death was due to marked *tissue destruction* proved by increase in the coagulable nitrogen estimated at the time of death.

PLATE I.

FIG. 1.—Liver of a Cat: Acute shock and death following the injection of autolyzed cat tissue. Shows portal zone of the lobule in which the portal veins are markedly congested, with coagulation of the blood. The liver cells in the periportal area show coagulation changes of the protoplasm.

FIG. 2.—"Toxic Shock" and death from the absorption of homologous autolyzed tissue products. Liver (high power): Portal and periportal zone of the lobule. Shows the protoplasm of the cells, tissue fluid and capillaries and large veins all coagulated. P, portal vein; C, capillaries congested and blood coagulated; C', the cells in the area where the reaction originates. The cytoplasm is coagulated. Necrosis and autolysis are already established. The nuclei refuse to stain.

FIG. 3.—Lung of a Cat. Shock injury 3 P.M., death 7.45 P.M. This shows capillary blood stasis and edema. Coagulation in the large veins complete stasis, giving the appearance of acute pneumonia.

FIG. 4. Lung of a Cat, injected with autolyzed cat tissue. Blood stasis in the lung. Capillaries in the pulmonary arterial zone of the lung. C', capillaries containing clotted blood.

FIG. 5.—Lung of a Cat. Experimental pneumonia in a cat; insufflation of the larynx with autolyzed lung tissue of the cat; death. Lungs show typical acute pneumonia.

FIG. 10.

PLATE II

ILLUSTRATING THE PATHOLOGY OF ISO-AUTOLYSIS, OR "PEPTONE SHOCK."

The relation between these Pathological Conditions and Antibodies.—As we appreciate the specific normal sensitiveness and the normal antibodies that occur in the body of an individual to his own tissue products, we will better appreciate the phenomena of disease and natural and acquired immunity.

Moyer S. Fleisher[30] shows that immunity tissue reactions play a more important part than do reactions produced by body fluids and that there is a difference between the effect of homotransplants and heterotransplants.* In homo-iso-immunization we see an increased leucocytic reaction due to direct action on the leucocytes. The difference that serum plays in the reactions about transplanted tissue is between the effect of immunization against homo-transplants and heterotransplants.

Loeb[31] has shown the absolute specificity of species reactions of the tissues, and states that "we must therefore conclude that this homo-response is produced through the vital, *specific* metabolic activity of the tissues."

Yoskio Suzuki[32] shows that in the tissue cells of the heart was found the neutralizing substance of native immunity.

In experiments *in vitro* W. K. Balls and John H. Korns[33] have shown that anaphylaxis reactions may not be specific, but that hemolysis shows species specificity even in the absence of anaphylaxis. In my work it was shown that specificity was clearly locked up in the animal species. The heart tissue produced the most active antigen in the causation of disease phenomena and was the most active agent in antibody production.

Treatment.—The "side chain" theory of Ehrlich has created a false conception in that while stating the processes of reactions it deceived many into the belief that real products had been formed which acted as specific antibodies, as, for example, "agglutinins" "precipitins," and the names of other substances which do not actually exist, though agglutination and precipitation do exist under certain conditions. Agglutination, clotting, clumping, and coagulation are results which may be caused by a variety of agencies. In the colloidal state in which protoplasm and the fluids of the body exist, mechanical means, such as shaking, may cause precipitation and agglutination, coagulation and clumping, b h *in vivo* and *in vitro*. A shake may therefore b called an "agglutinin," a "precipitin," etc. Heat nay reverse the order by dissociating an adsorption compound and therefore acts as an "antibody."

By placing our conception of the antigen and antibody reaction in the field of colloidal chemistry our knowledge of the "reversible colloids" of the body is better comprehended and applied to the facts we already know. Thus coagulation, clumping, and clotting, and certain other colloidal reactions may be reversed by heat if it is applied sufficiently early, whether the application is made in the body or in the test tube.

When adsorption takes place between two colloids the reaction depends not on the mass of the substances but on the surface. When a substance reaches the surface to which it is to be attached the reaction or the process we call "adsorption" takes place with great rapidity. The action therefore, on the cell processes can be, according to Warburg,[33] excited by substances which do not penetrate beyond the surface of the cell. As Bayliss observes ("Principles of General Physiology," p. 60), "In specific adsorption when the surface of the cell takes up preferentially a particular substance, as iso-autolyzed polypeptids, it seems unlikely that recourse need be had to chemical phenomena." The changes that primarily occur in the splanchnic area in shock and infection and a variety of conditions are congestion, high viscosity, and stagnation of the fluids in the splanchnic visceral area. This colloidal state of adsorption to become reversed must

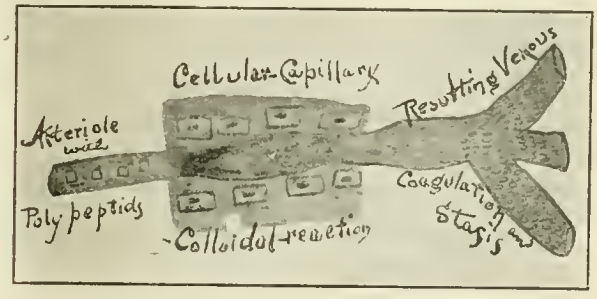

FIG. 11.—Schematic presentation of the pathology. This shows that no action takes place until the polypeptids come into contact with the surface of the cells; then adsorption from surface tension causing the colloidal reaction with the coagulation of the tissue fluid, extending into the capillaries and venules and advancing into the larger vessels. (Compare with Figs. 2 and 4.)

be accomplished during the time when a reversible reaction is possible, and again it is impossible to attempt to produce a reversed reaction by applying the reagent to a locality too remote from the source of reaction.

Nothing is more evident in this war than that for counteracting shock in the badly wounded the only reliable method was the continuous application of heat. In some cases it required forty-eight hours *continuous application*, but the heat should be applied more directly to the splanchnic area, as I have demonstrated, experimentally and clinically,[36, 47, 48, 50] both as a preventive and as a curative measure.

To illustrate: If gelatin has coagulated in a test tube we place it in warm water to cause a reversal of the colloidal reaction, and it again becomes liquid; if we cover the test tube with a non-conducting medium, then, even though placed in hot water, no reversible action can occur. In cases of shock and infection, heat to be effective must be applied as nearly in direct contact with the splanchnic area as possible. The application of hot water

*M. S. Fleisher[29a] makes the following statement: 'There are striking differences between the histological appearance in the pieces of kidney tissue transplanted into immunized animals; furthermore, there are differences in the rate of progress of events."

PLATE II.

FIG. 6.—Stomach. Blood stasis due to coagulation produced in acute shock; the coagulation begins in the capillaries in the mucosa and extends into the large veins in the submucosa ("zona transformans").
FIG. 7.—Lung. Mechanical shock; acute general coagulation.
FIG. 8.—Intestine of a Dog. Subacute toxic shock; dilatation of the veins with contraction of the arteries. The blood congestion begins in the venous capillaries of the mucosa and extends down into the submucosa.
FIG. 9.—Lung of the Human. Hospital case. Shock and death following injuries from an automobile accident. The lung shows the same congestion of "pneumonia pathology" as is found in our experiments on shock in animals.
FIG. 10.—Lung of the Human. Hospital case. Acute pneumonia and death three days after an attack of influenza.

bottles to the surface of the body is too remote to be of value, even though they are applied to the abdominal wall. I have long advocated the use of small thin rubber hot water sacs introduced into the abdomen during surgical operations. The rubber surface is preferable to the injurious gauze, as it causes less trauma to the peritoneum and provides a more constant heat, which to be effective must be of high temperature as well as directly applied.[50, 68]

Where the abdomen is not opened the next approach to the splanchnic area is through the stomach. The small rubber sac above described is attached to a double recurrent rubber tube and introduced into the stomach. The heat is maintained continuously by a constant inflow and outflow as I described in 1896.[67] The heat not only reaches the liver by the gastric veins but the thoracic area through the esophagus is more or less directly affected, thus preventing stagnation in the lung capillaries. These methods can be used throughout surgical operations and have been found to lessen the danger from anesthesia. The colon is the next valuable avenue for heat application to the splanchnic area. Hot water introduced into the colon during surgical operations is not always practicable, but the small hot water bags introduced into the colon can be beneficially used, though heat applied here is not always as effective as by the more direct route, the esophagus and stomach. I have for many years[49] advocated the use of the continuous irrigation of the colon (with the double recurrent tube, giving water of high temperature followed by cold; then repeated) in operative or accident cases and infections of various types. As a control to regulate the amount of water, the outlet tube is connected with a vacuum bottle at the bedside which does not allow the colon to be overfilled. The heat and absorption of the water have been shown to be of great value in all cases of shock and infection. The idea of the absorption of water alone without the heat led to the adoption of this method as the "Murphy drip." The danger of the injection of water by the colon, subcutaneously, or intravenously, was shown early in this work, and hence caution must be maintained by the proper dosage of the fluid intake. The value of this continuous fluid absorption and persistent heat within the abdominal area with the hot water bag will be more appreciated now that we know through our researches in colloidal chemistry that heat dissociates an adsorption compound which occurs in the "colloidal complexes" in the animal organism in shock and infection. The application of heat to the soles of the feet has the advantage of being more direct in affecting the splanchnic area than when applied to the trunk, for the blood in the plantar veins when heated is carried directly by anastomosis through the hemorrhoidal vein into the splanchnic area, portal vein of the liver, etc.[68]

Specific Immunization.—Antitoxin and Antigens: Chemical injuries of the body cause cell necrosis, the products of which evolve a poison—polypeptids. These products cause a *reaction* which produces what are termed *antibodies* against the poison and its effects. Polypeptids, though formed from the tissue of the individual, act not as foreign protein but are specific for that individual. This may cause sickness and death if produced in sufficiently large quantities, but if the poisoning is repeated in smaller doses, it causes certain well known specific reactions associated with the formation of antibodies and the creation of immunity by the individual against his own protein poison. That is, man's own tissue is not only his specific poison but the producer of his specific antitoxin.

Normally there is a physiological equilibrium between the toxins of tissue necrosis and antitoxin production. In disease the mechanism requires a more abrupt stimulation to produce sufficient antibodies which we attempt in our treatment by producing *active* immunity. Passive immunity is also employed. Horses injected with necrosed human tissue produce antibodies, the serum of which injected into patients establishes a specific passive immunity. The combination treatment by active and passive immunity gives the most brilliant results.

Native Protein.—To create active immunity in combination with passive immunity, chloroform is injected into the tissues, about three or four minims (¼ c.c.) at each selective point. Cell necrosis follows each injection and specific active antibodies are created. The *native* protein liberated by the chloroform injections is specific to the individual and is far more valuable than any foreign protein which I have tried over a period of many years.

Many other cauterizing agents were used in our experimental work and found to produce the same results, as were observed with the use of chloroform. The writer found that cauterizing agents, such as silver nitrate, chromic acid, formalin (Attidell' Xl, Cong. Med. Intern., Vol. 111, Med. int., Rome, 1894; Eine neue Methods der Diagnose end Therapie gewisser Magenkrankeiten und bakteriologische Studiem bei denselben, *Wiener Med. Wochenschr.*, Nos. 1 and 2, 1895), mustard oil,[38] chloroform,[43] applied or introduced into the body was followed by varying degrees of intoxication and in sufficient dosage caused death. Death was caused by the absorption of the products of cell necrosis. Repeated small doses finally ceased to produce the effect because the natural antibodies were increased against the cellular toxins in the animal. Mustard oil caused necrosis deep in the tissues and specific immune bodies were formed.[38] To quote from my article describing other experiments: "Repeated injection of the extract from the mucous membrane and an emulsion of the membrane produced no evidence of fatigue of gastric muscle. Examination in five experiments revealed a destruction of *gland tissue* of the *stomach*. The necrosis was especially noted at the lesser curvature and the pyloric region of the stomach."[57]

It was found, in 1903, that the chloroform produced cell necrosis which established the best active specific antibodies. The resulting elaboration of toxins produces symptoms of "autointoxication" associated with hemolytic agglutinating bodies and precipitins."[43] Nitrate of silver, when applied to the mucous membrane of the stomach and duodenum forms the "albuminate" of silver and cell necrosis. Intense hyperemia of the mural structures follows and the products of cell necrosis are carried into the liver, there causing intense hyperemia. Antibodies against cell necrosis are produced and this was found by the writer to be the beneficial effects

of the nitrate of silver treatment in peptic ulcer (MEDICAL RECORD, June 24, 1916), but additional passive immunizing serum must be injected simultaneously to obtain complete cure in peptic ulcer.*

Foreign Protein.—Foreign protein injections in addition to native protein treatment have been used by the writer for many years, in various classes of cases, including peptic ulcer. Diphtheria antitoxin has also been used, "which seems to exert a polyvalent effect." The intestinal flora was also used for the preparation of vaccines in connection with serum treatment.[60]

In 1906 fetal muscle juice, split by bacteria, was injected in cases of peptic ulcer. Autogenous intestinal flora were injected into fetal animals and incubated for 48 hours. The fetal meat juices were then pressed out under heavy pressure and after fractional sterilization this foreign protein was injected into patients suffering from various conditions, among which was peptic ulcer.[64] I attempted to make the foreign protein of bacterial vaccine therapy specific to the individual by autolyzing the patient's serum with autogenous bacteria cultures and injecting the combination.[65]

Although *foreign proteins* injected were found to bring relief in many cases, it was not a reliable form of treatment. In those cases in which improvement in symptoms seems to occur in the course of treatment it was seldom permanent. It lacked the specific effect that is furnished by the individual's own tissues.

We subjected this problem to controlled experiments. A number of cats were immunized with a specific goat serum prepared by intravenously injecting the goat with cats' autolyzed tissue. As controls a similar number of cats were injected with plain goat serum. These cats all received lethal doses of autolyzed cat tissue. All the cats injected with plain goat serum succumbed, with shock symptoms followed by death. The cats immunized with the specific cat tissue serum survived. These experiments were made repeatedly before and after lethal doses, and it has been proved that the specific immunization protects while foreign protein injections do not; they may be a useful adjunct but are unreliable. Cases treated compared with immunity experiments in animals give the most convincing evidence and support to the principle on which the treatment is founded, "For the principle seems to be more than half the question." (Aristotle, Ethics, 1, 7.)

Specific Immunizing Serum.—The immunizing serum is made by the intravenous injection of human autolyzed tissue into horses. Small injections are made into the jugular vein of the horse two or three times weekly for six months until a high titer of antibodies is created. These antibodies are tested against human cell products *in vitro* and further biologically tested. Comparisons are made with animals immunized with goat "antitoxin" serum. This is made by injection of the goat with animal's autolyzed tissue specific to the animal used. Various portions of the human body are used for the antigen. The heart seems to give the most polyvalent effect. Gastrointestinal tissue in ulcer work and respiratory tissue, including lung tissue, are used for antigen for producing a serum used for immutization in respiratory diseases.

Dosage and Number of Injections.—In the beginning of the course of treatment we inject three to four minims of chloroform at each selected point. This is followed by the separate injection of the specific immunizing serum, using 3 to 50 c.c., according to the demands of the condition. The number of injections is also a matter of the physician's judgment. In many acute conditions one or two large injections are all that is required. In subacute and chronic conditions several injections are used, about two or three days apart. After the initial injection of chloroform it may be later discontinued and the antitoxin injected alone. Slight redness will occur and sometimes the usual rash, but this has not been so constant as in the use of ordinary serum injections. We have seen no untoward results and none have been reported. All testify that it is practically harmless.

Cases Treated.—I have used the different specific sera in a large variety of conditions, among which may be mentioned the following: Shock; wounds, recent and old infected wounds; pneumonia, asthma and other respiratory conditions; peptic ulcer; acute neuritis, and multiple and single neuritis; chronic neuritis; rheumatism, muscular and arthritic; arterial sclerosis, with and without kidney lesions.

Twenty-eight cases of shock following various injuries were treated under my direction, all of which recovered except three. Two of these were cases of severe burns which died on the following day, and the third was a compound, comminuted fracture of the skull with hemorrhage and escape of brain substance. Eighteen wound injuries that failed to heal under ordinary treatment were injected with the immunizing serum. This was followed by rapid healing and recovery. Many other cases of fresh wounds that have been injected have shown rapid healing. These cases will be reported separately and in detail.

The following table shows the results obtained in cases that had been previously treated, some over an extended period of time, with foreign proteins injected intravenously and subcutaneously without producing a cure in any instance. These patients had had the best medical care, some being under clinicians of international reputation. The examinations were carefully made and checked up at the different institutions where many of these patients were treated, and included biological tests, *x*-rays, etc. Many of these patients had received treatment in sanitariums and health resorts which had failed to effect any lasting benefit. Nearly all these cases are now permanently cured. All showed relief from their symptoms from the beginning of their course of treatment. The cures reported have been closely followed by physicians in a position to judge of the extent and permanency of our results.

Our treatment consists in the injection of the

*In deep-seated infections and many neuralgias and other pathological conditions chemical cauteries are used, not only by veterinarians, but are repeatedly used by the best surgeons for the same reason that the actual cautery is used, namely, to cause cell necrosis and the specific reaction that follows. By this means the patient has often been spared débridement or amputation. We are now able through our experimental research to place our old empirical methods on a solid scientific basis.[51, 52, 70]

specific antitoxin described in this paper, the dosage being from 2 to 10 c.c. at each injection, and the number of injections running from 3 to 10 in all.

Summary.—1. Mechanical, physical, or chemical injuries produce definite pathological conditions of a constant character. Mechanical and physical injuries are followed by changes in the organism that may be indicated by the schematic figure 12.

2. Destruction of tissue results in cell necrosis, cell digestion, and specific toxic products, as shown in schematic figure 13.

3. Destruction of tissue from injuries admits secondary invasion by bacteria which increases the velocity of cell necrosis and cell digestion, augmenting the production of the toxic products, as shown in schematic figure 14.

4. Reactions that now arise in the organism create secondary conditions—the formation of antibodies accompanied by symptomatic variations. (Fig. 15.)

5. When the response of the organism to the reaction is insufficient, active immunity is induced by repeatedly injecting the antigen in small doses. The antigen may be created within the organism by small repeated injuries. This creates cell necrosis and resultant antigen products and finally active immunity. (Fig. 16.)

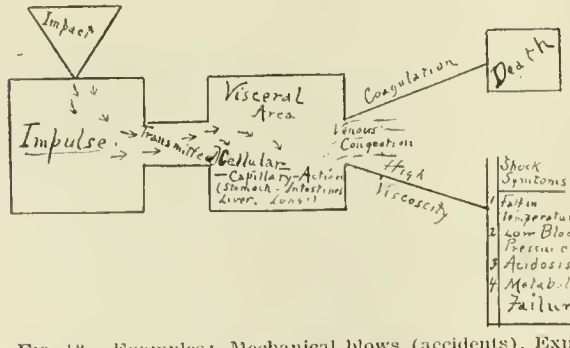

Fig. 12.—Examples: Mechanical blows (accidents), Explosions (sudden air compression and decompression). "Caisson disease," Shaking (car sickness, sea-sickness, etc.)

6. Autoactive immunity cannot be relied upon when the immunity productive power of the organism is weakened by disease or is inherently deficient. The creation of antibodies in an animal by long repeated injections of the human tissue antigen produces a specific serum. This furnishes passive immunity in conjunction with the above active immunity which is specific. (Fig. 17.)

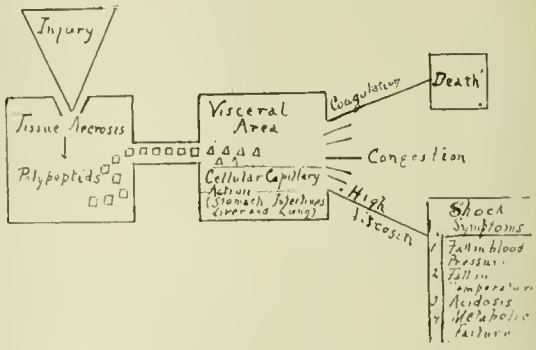

Fig. 13.—Examples: Traumatic injuries, Chemical caustics, or actual burns.

Conclusions.—1. "Shock" wound "disease," with and without infection, and other diseased conditions are caused by cell necrosis, cell digestion, and resulting toxic products.

2. Specific antibodies are normally created and may be artificially produced which are protective and curative.

3. Others[31a] have noted cell necrosis and that its products are responsible for disease, and also that specific tissue immunity can be attained, but we have by twenty years of laboratory and clinical work established a basis by which it may be possible to solve the more intricate underlying etiology of disease and the problems of practical therapy.

EXPERIMENTS.

The primary change which took place in all the following shock experiments was the same in every instance, varying only in intensity, degree, and extent. Observed through a small lens during the progress of shock, the venules showed in all cases the first signs of congestion, while the arterioles contracted somewhat. The phenomena was therefore primarily a venous stasis of the venous current, originating in the venous capillary area.

When the action was abrupt coagulation was immediate, but when less severe the degree of stasis depended upon the degree of hyperviscosity produced. This was observed in the liver, stomach

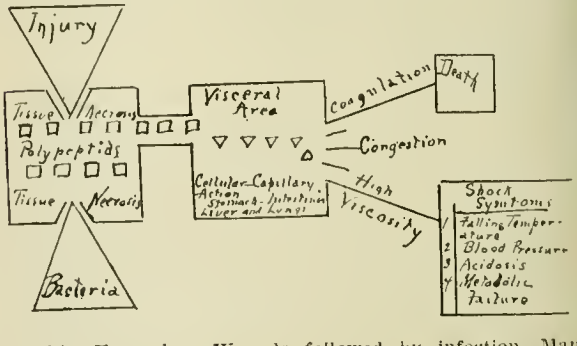

Fig. 14.—Examples: Wounds followed by infection. Many acute and chronic conditions.

and upper intestines, and on opening the pleural cavity the lungs showed the same congestion. Frozen sections, made immediately, demonstrated that the reaction was a colloidal phenomenon of adsorption. The protoplasm of the cells initiate or

take part in this reaction, which is transferable through the fluids and capillary areas, resulting in stasis and checking the return flow of blood to the heart.

In the liver a demarcation zone showed stoppage

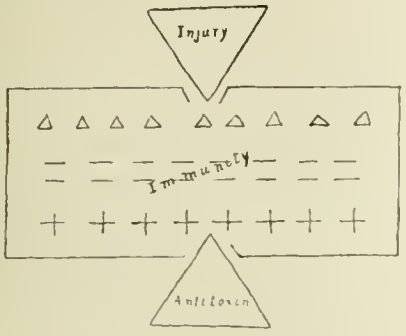

Fig. 15.—Examples: Natural immunity.

of the return flow of blood to the heart, while in the stomach and intestines it took place between the mucous and sub-mucous layers (zona transformans) and on opening the pleural cavity the same congestion of the lungs was seen.

Microscopically I observed in cases that had been long in shock that in addition to the chronic congestion many of the cells were in the early and late stages of autolysis or necrosis.

The following is a resumé of the various methods employed to induce shock and of the changes seen. The protocols for each one have many controls.

1. *Mechanical and Physical.*—(*a*) Blows (accidental falls, intentional tappings); (*b*) shakes (produced in shaking apparatus); (*c*) air compression (explosions, guns, etc.); air decompression.

Series I.—In this series mechanical, physical, and chemical injuries were produced in the animals. Impact against the body, or percussion, or shaking in the "bottle shaking" apparatus, shell explosion in the "shock box," air compression and decompression, all produced similar conditions of shock. When these forces were used with sufficient velocity, the impulse from the impact against the body was transmitted by the body fluids to the visceral area and caused here coagulation, shock, and death.[36] In the less violent procedures primary changes were observed in the open abdomen with a small magnifying lense. The blood stasis was studied in frozen sections or immediately hardened on fixing agents. These demonstrated that the stasis occurred in the capillary areas. The cellular reaction was always manifested by apparent coagulation of the protoplasm, the agglutinating blood backing down into the venules and to the large venous vessels. Sections of the fresh intestine with the retained blood

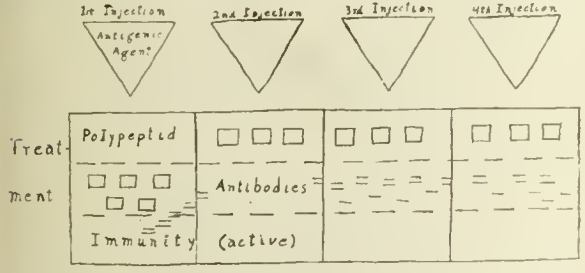

Fig. 16.—Examples: Actual cautery, or Chemical cauteries, etc.

were resected and portions of the fresh muscle when placed in the "shock box" with tubes of gelatin, fresh drawn blood and muscle plasma clotted at once on discharge of a shell. This was due to the impulse imparted to the particles in the colloidal suspension causing the usual adsorption phenomena.

The animals used included cats, rabbits, monkeys, guinea-pigs, horses, and goats. In this series eighty animals were used.

Series II.—In this second series injuries were produced to cause disintegration of the tissue. Instrumental mangling of the *tissue* and also the injection of cauterizing agents, such as chloroform, to produce cell necrosis under *aseptic* conditions. When cell necrosis by either instrumental or chemical destruction of the tissues occurred polypeptids were formed, giving all the usual polypeptid chemical reactions. These polypeptids on absorption caused congestion changes in the vessels, stomach, intestines, liver, and lungs, resulting in shock and death in from three and one-half to twenty-four hours. Removal of the products from the tissue and injection intravenously into the same animals caused instant death or death within three minutes, with acute shock symptoms and characteristic

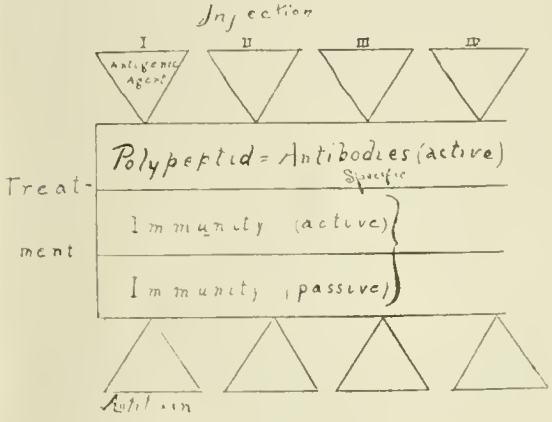

Fig. 17.

pathological congestion in the stomach, intestines, liver, and lungs. Early removal of the disintegrating tissue, either that resulting from instrumental or chemical injury (injection of chloroform) and immediate suture prevented death in many instances. Later efforts at removal were not as successful.

A portion of the animal's tissue was placed in an incubator for several hours and autolyzed under antiseptic conditions. On intravenous injection of an emulsion of 1 or 2 c.c. either instantaneous death or death within a few hours ensued. Foreign proteins injected did not, as is well known, cause death unless the subject was previously sensitized, but autolyzed necrosed tissue cells, taken from the same animal (iso-autolyzed tissue), and injected back into the animal did not require previous "sensitization." The pathological changes that take place from the effect of the "chemical poison" (iso-polypeptid) produced a similar blood stasis to that seen in shock experiments of Series I.

Controls.—Animals injected with small doses, 0.25 c.c., 0.2 c.c., chloroform in repeated doses recovered and finally became immune to their autolyzed tissue after the large chloroform injections.

Cats injected subcutaneously with cat homologous tissue with the addition of chloroform all died from shock in twenty-four to forty-eight hours, as shown by the following table schema:

Injected subcutaneously autolyzed homologous cat tissue plus chloroform	Cat J. J.	Injected subcutaneously homologous cat autolyzed tissue plus chloroform.
	Death in two days.	
Injected homologous autolyzed cat tissue.	Cat K. K.	Chloroform, 1 c.c.
	Death in 24 hours.	
Injected 1.5 chloroform.	Cat L. L.	Injected 1 c.c. chloroform.
	Death in 24 hours.	

SERIES III.—In this third series studies were made of the lung changes in shock experiments. Iso-autolyzed muscle tissue, when injected into the animal, caused immediate hemorrhages in the lungs, with clotting of all the capillaries, followed by death. Small doses often repeated caused more subacute and chronic changes. Very small doses administered subcutaneously produced immunity. Wounds if left open even under aseptic conditions produced similar changes in the lungs. The most characteristic changes in the lungs were effected by spraying or insufflation of homologous autolyzed *lung tissue* into the nasal chamber and larynx of the animals. The autolysis was accomplished under sterile conditions. At the end of eight to ten days a second insufflation of the lung tissue caused acute pneumonia, congestion, and death in a few moments. Smaller doses produced typical pneumonia symptoms, some lasting seven days before death occurred; other animals recovered. The lung changes, as shown in the microphotographs, are the classical changes one sees in pneumonia. Both the bronchial and the lobar types were produced.

Experiments producing special lung congestion: (*a*) Autolyzed muscle (large and frequent dose, causing sustained shock); (*b*) traumatic wounds (severe and unprotected, with continuous shock); (*c*) lung tissue (spraying or insufflation into the larynx; the results varied in degree, some being acute, some lasting seven days, and some recovering).

Controls.—Spraying pneumococci of types I, II, III, and IV, and streptococcus hemolyticus, separately and combined, produced no pneumonia in any instance. Injecting cultures intravenously or subcutaneously likewise yielded negative results. Cauterizing agents, such as insufflation with acids or chloroform, might cause pneumonia symptoms. This is due to the autolyzed necrosed tissue of the respiratory tract, the microorganisms found later being only secondary invaders.

SERIES IV.—*Infection and Immunity.*—The fourth series of experiments were similar to the ones just cited, with the exception that bacterial cultures were added to the injuries. The primary effects of bacterial invasion showed no difference in the symptoms or pathological changes produced in the animals other than an increase in the rate of formation of polypeptids by supplanting the digestion of the cells. As the writer's previous experiments showed,[42] cell necrosis and shock are necessary conditions to insure rapid bacterial growth in tissues.[43, 50]

Injuries produced by instrumental means, actual cauterys (burns), or chemical cautery prepared the soil for bacterial growth. By first causing injury to the muscle tissue, an open wound, as in the ordinary production of aseptic shock, was inoculated with cultures of *B. coli, B. welchii,* staphylococci, and streptococci, previously grown on homologous necrosed muscle tissue, by injecting and spraying into the wound and allowing to further develop. After this procedure animals succumbed within a few hours with the identical conditions of shock-fall in temperature, fall in blood pressure, and stupor. Heart and lung puncture showed no bacteria and no bacteria were found in the blood. The post-mortem gave the same pathological findings demonstrated in aseptic shock.

A.—*Experiment.*—1. After cleaning the surface of the mucosa of the duodenum and jejunum of rabbits, the mucous membrane was scraped off from the muscle wall and discarded. The submucosa was then removed, so that none or but little of the gland elements remained. The submucous tissue and fluid was recovered. To this a culture of *B. coli* was added to a 2 per cent. suspension and incubated. Injection into rabbits of this product of homologous cell autolysis of rabbits caused shock and death.

Controls.—Injecting submucous substance in the fresh state in large quantities shock and death did not occur. The same *B. coli* cultures when injected alone gave negative results.

2. Injection into fetal pigs (as fetal animals are sterile) of *B coli* and *B. welchii* and incubated for twenty-four hours caused rapid autolysis of the tissue cells. Injection of this product, pressed out from the tissues, caused death from shock.

Controls.—Injection of *B. coli* and *B. welchii* alone have negative results. Injection of fresh fetal cells gave negative results.

B.—*Infection and Immunity Experiments.*—1. Active.—Animals immunized by several injections of their own tissue under aseptic conditions.

Results.—(*a*) Wounds and infections of *B. welchii,* streptococcus, and *B. coli,* staphylococcus aureus, could gain no hold and the wounds healed without treatment. (*b*) Normal animals as controls succumbed to shock produced by the rapidly autolyzing "infected" tissue.

2. Passive.—Animals made passively immune by the shock antiserum produced in goats.

Results.—(*a*) Similar to those of the actively immune, no autolysis, no infection, no shock, rapid healing of wounds. (*b*) Normal controlled animals succumbed to rapid disintegration of tissue, bacterial growth and shock.

The results of these experiments make the fact stand out boldly that the rôle played by the bacteria is simply to increase the amount of toxins produced by increasing cell digestion, and that the cell toxins produced are the agents causing the further necrosis and against which immunity is to be established and not against the bacteria.

The animals used in similar experiments and the details of the protocols are so extensive that it is not feasible to publish them all in the space at our command. It may be recalled that illustrative protocols have been published by the writer in connection with several previous communications along these lines.[51, 52]

14 EAST FIFTY-THIRD STREET.

Pappataci Fever.—Interest in this affection has been aroused by the influenza pandemic. Gabbi states that it is known to occur in Switzerland as well as in Italy and the Balkans. Its nature is fairly well understood since it is due to a filtrable virus and transmitted by the sandfly. It is transmissible only during the 3 days febrile period. It comes on without prodromes, with fever, severe headache and myalgia. In about one-fourth of the patients there are anorexia and vomiting. There is a very slight angina and in the more severe cases slight albuminuria. The skin is dry and burning and the conjunctivæ injected. The blood presents typical leucopenia. Complications sometimes seen include bronchitis and hemorrhagic nephritis. A fatal case has never been recorded.—*La Presse Médicale.*

SUGGESTIONS FOR A NATIONAL MUSEUM OF MEDICINE.

By R. W. SHUFELDT, M.D.,

WASHINGTON, D. C.

THIRTY years or more ago I contributed a paper to *Mind in Nature*, of Chicago (February-March, 1886), entitled "Science and the State." It was republished in full by *The New York Medical Journal* of May 22, 1886 (separata 50, repaged), under the same title and without change. No sooner had it appeared than the press gave it great publicity by taking up its subject matter, and, still without change of title, discussing it from various viewpoints. Likewise, in England, it deeply interested Sir Lyon Playfair, who promptly exploited the questions touched upon in the contribution in certain publications in London, and, further, favored me with a letter, in which he expressed his appreciation of the part I had taken in the discussion. Sir Lyon was interested for the reason that London, or rather the British Parliament, had under consideration at the time identically the same problems that confronted us in this country, and these were gone over in considerable detail in the article referred to above, entitled "Science and the State." In the main, the attempt was made to point out the unnecessary waste that was annually taking place with respect to the handling of the Federal bureaux; the use and disposition of scientific researchers in the Government's employ, and the remedies for adjusting all such and allied matters. Very fully it was shown that an enormous waste was continually going on upon account of the duplicature of buildings, of collections, of libraries, and the various necessary concerns attached to them. There were also in operation many archaic regulations and laws that made directly for the suppression of scientific work, when undertaken by officers of the Government, whether in the army or naval service, or other departments. Even when it in no way interfered with their prescribed duties, officers were sometimes severely handled and even persecuted with great cruelty for utilizing their spare hours in carrying on some special research work or other in technical science. The recorded history of our military organization in the past contains quite a number of instances to exemplify such practices during the last century, as will be appreciated through a reading between the lines of "Science and the State."

Several changes making for economy and greater efficiency are pointed out in the above-mentioned article; and, although many years have elapsed since its appearance, but very slender improvement has been made in such premises.

The great world war, now apparently drawing to a close, has revolutionized, to their very bases, many of our institutions—public as well as private. It has opened our eyes to many states and conditions in our national organization that we either saw but dimly, prior to the outbreak, or else did not appreciate at all. Indeed, the various effects produced are so radical, and in most instances so far reaching, that to touch here upon even a few of them would be quite out of the question—or were the selection made among those that obviously fall within the limitations of the field suggested in the title of this article. This being true, I will at once enter upon what I have in mind to discuss, namely the propriety of establishing a National Museum of Medicine at Washington—and the suggestion is made distinctly in the light of what was, so long ago, pointed out in my "Science and the State" contribution.

To many it is a well-known fact that we have, in Washington, a curious array of army, navy, and other medical institutions, each supporting expensive plants or equipments and libraries, ranging all the way from a thousand volumes or so to one carrying more than three hundred times that many on its shelves. Such an arrangement calls for a professional personnel in each case, with a standing force of clerks, messengers, and general helpers of various classes. These several institutions support, in not a few instances, working laboratories; large collections of material, or museums, established and conducted along lines leading to public and professional instruction; morgues; dissecting-rooms; research-tables, and the requirements to meet forty and one other ends. These dissociated centers, taken as a whole, rarely or never act in unison upon any Federal demand on them, or offer to the public, in their entirety, an accessible, centralized resort, where any desired class of information may be secured with the maximum amount of convenience and the minimum loss of time and effort. As now constituted, they present a state of affairs the very reverse of this, for we have a dozen or more centers of the kind, located at widely separated points in the city.

As an example, we may take the institution long known as the Museum and Library of the Surgeon General's Office of the Army. Over thirty years ago, this truly unique, and to some extent distorted concern, consisting of really a wonderful library and a heterogeneous collection of medical, surgical, biological, and miscellaneous specimens, came to occupy its present quarters—a very unmuseum-like building at the corner of B and Seventh Streets in Washington. Taking into consideration the way in which this institution came into being, and considering also the nature of its growth, it is not at all to be wondered at that the Medical Department of the Army tenaciously clings to the right of having it wholly under its control and domination. In reality, however, this inherent right rests more upon a foundation of sentiment than upon what in truth should come to pass, as a step to vouchsafe the greatest amount of benefit to the people as a whole. The library is now one of the most splendid assets of this nation; and the heterogeneous collection of specimens in the museum, numbering thousands, has interested, instructed, and amused the profession as well as the general public for half a century or more. Extensive as it is, however, this collection by no means illustrates the subject of medicine, when taken in its entirety, as a museum most emphatically should do, be it a civil or a military one; this especially in view of the fact that, in the instance cited, it is supported and provided for by the Federal Government.

Take, for instance, the important branch of materia medica; practically no attention has been paid to the subject at this Army Medical Museum, while in the National Museum—near at hand, to be be sure—is one of the finest collections of the kind in ex-

istence, the assembling of which was largely due to the energy of Dr. James Flint, of the Navy. And so it goes for a number of other departments—indeed, as a matter of fact, for altogether too many others.

The very important subject of Hygiene seems to have been taken care of by the Navy—with another added medical library. There are Government chemical bureaux, with chemical libraries forming a part of several of their main departments—a most expensive arrangement for the Government; while a far more economical and efficient one would be to have one extensive chemical bureau, equipped in all particulars to meet any demand the Government might make upon it, and that bureau occupying a suitable building, with its various sections, in the immediate neighborhood of our National Museum of Medicine. The Chemical Museum should form a part of the main National Museum, and the material placed on exhibition in it should illustrate every imaginable appliance used in every line of chemical research as well as the science of chemistry as a whole.

The same arrangement should apply to medical entomology—a most important branch of not only military medicine but as affecting public hygiene. In fact, a department of Public Health and General Sanitation, with an up-to-date series of laboratories and every possible facility for research and demonstration work, should be confined to another building near the chemical one, and harmoniously worked into the general group. Its library should be a sectional one in the general library of the main central building. This offers a special advantage, as research students in medical chemistry frequently find it necessary to consult other works in connection with those on their own science; and it ought to be unnecessary to be compelled to go to some entirely different section of the city to find the other required works, to say not a word as to the loss of valuable time and cost of transportation. Apply this to the Regular Medical Corps of the Army to-day, with its Dental, its Sanitary, its Psychological, its Veterinary, and its other Corps; add to these the corresponding ones in the Navy, Marine, and other Departments, and it would be difficult to conceive of a more expensive arrangement, in so far as the Government is concerned, or a more inefficient one with respect to loss of time and opportunity for concentration of effort on the part of the various officers and researchers.

Consider for a moment what an advantage it would be to the various departments of veterinary science to nationalize them as a whole; to have an entire section in the main museum building given over to their collection, and to have a complete veterinary library in the main National Medical Museum library, with a group of buildings harmoniously disposed in the general plan—close at hand—where dissecting rooms, serum laboratories, operating rooms, with quarters for the veterinary pathologists, anatomists, and physiologists may be found; in fact, separate buildings—where necessary—for every modern line of veterinary work and inquiry. A moment's thought is sufficient to convince any professional man of the supreme advantage of this arrangement over what obtains at the present time in this field in the Army.

There should be identically the same plans for the comparative anatomists and physiologists, including the college of experimental researchers, morphologists, and those engaged upon vivisectional investigations. In connection with the latter, there should be a section to supply promptly the various animal forms so constantly required in such work.

Among the museum halls in the main museum building there should be one in which an extensive and complete collection and exhibit, demonstrating vivisectional work in each of its departments, should be found; this to be so arranged and scientifically displayed as to not only forcefully demonstrate the absolute necessity for the work done in that department, but also the enormous aid it has been in elucidating some of the most important problems in general and special diseases and their treatment, as well as solving problems in human physiology and adding materially to our knowledge in special lines of research, that have for their purpose the advancement of those sciences, the relief of human suffering, and the treatment of our domestic stock.

The Army and Navy Medical Schools should occupy the necessary buildings in the main group; and the advantages following upon their being associated in that way are altogether too obvious to require any discussion.

As to the site for this National Museum of Medicine, it should not be less than twenty-six acres in extent, with an accessory acreage for the Veterinary Department. The whole should be attractively situated, and chosen to meet all the requirements of the institution. A special line of cars should connect it with the street railways of Washington; it should be extremely easy of access at all hours, and require but a brief time in which to reach it from any central point.

As to the Library of the Surgeon General's Office, at present installed in the aforesaid Army Medical Museum, magnificent as it is in the matter of the number of books, journals, pamphlets, manuscripts, photographs, and other precious belongings, it now stands sadly in need of a complete rearrangement. This subject, however, does not fall within the limitations of this article for discussion. It is not altogether an easy matter to find a good, scientific librarian nowadays, one who has mastered all that modern librarianism means, and who has the physique and the necessary training to apply it.

Added to the main offices in the Administratior Building of this National Museum of Medicine, there should be an up-to-date Auditorium, with all the modern fittings for lecturers and demonstrators, including the best of motion picture equipments and other appliances. There should also be a first class photographic gallery and art department, capable of producing every conceivable class of photographic work, micro-photographs, and all that has been perfected up to the present time, including radiograph work, enlargements, copying processes, and so on. The art department should be equally complete, and so arranged as to successfully work hand in hand with the corps in the photographic gallery and rooms.

The dissecting rooms should be of the most modern order possible, and every convenience and contrivance for the highest class of work installed. There is at this time, I am told, a very superior dissecting room at the Army Medical School, which

latter is situated at a considerable distance from the Army Medical Museum. How much more efficient would this arrangement be were it on the same grounds with the Museum, where the students could, in a few moments, compare specimens in the Museum with the material under their hands on the dissecting tables.

The present Museum building has very little to recommend it for the purpose for which it was erected. Although four stories high, it has no elevators of any kind; most of its work-shops are in a dark and poorly ventilated basement; its stairways are of an uncomfortable type; the lighting is faulty; the dissecting room small and otherwise inadequate for the purpose for which it was designed; there is no proper auditorium, nor shops for preparateurs, not to mention other shortcomings.

Let us build for the future; and when Congress comes to appropriate with the view of placing these most necessary sciences on a substantial footing, in keeping with America's aims in such matters, let it be for a National Museum of Medicine, rather than perpetuate a decidedly one-sided institution, such as now exists.

3356 Eighteenth Street, N. W.

THE MEDICAL TREATMENT OF APPENDICITIS.

By ALBERT ABRAMS, A.M., M.D., LL.D.,

San Francisco, Cal.

In the presence of abdominal pain, the surgeon who uses his head as well as his knife thinks of appendicitis, but, when he uses his knife to the exclusion of his head, he thinks of nothing else. Every physician has his visceral fetish and the tendency to patronize definite organs and methods of treatment is rampant. There is the gynecologist whose conception of disease is limited to the uterus and adnexa, and there is the oculist with mental astigmatism, who reflects his subjectivity in the examination of his patients.

Thus it has come to pass that the treatment of appendicitis has been preempted by the surgeon as his prerogative and the delinquencies of the medical art already rebuked by satirists is accentuated by the attitude of the surgeon. Eliminating errors of diagnosis, notably conditions specified by the writer as pseudo-appendicitis,[1] one must concede that, as a rule, acute appendicitis is a surgical disease for which there should be no medical treatment. This much the writer concedes but he is reluctant to subscribe to the impotency of medical intervention in all cases of chronic or recurring appendicitis.

The methods of spondylotherapy have been firmly intrenched in medical practice and Jarvis,[2] Snow,[3] and others have definitely shown by skiagrams the effects of these methods when correctly executed. In brief, spondylotherapy[4] concerns itself with the excitation of the functional centers of the spinal cord by different methods. Each segment of the cord is a unit endowed with motor, sensory, vasomotor, trophic, and reflex functions. In the cord there are centers for the contraction and dilatation of the viscera. Practically all the visceral reflexes described by the writer have been elicited by Jarvis[5] at the operating table in anesthetized subjects with a strong sinusoidal current as described in spondylotherapy. The writer has shown that the manipulations of the osteopath and chiropractor yield results not by reason of replacing so-called displaced vertebræ but by the unconscious elicitation of visceral reflexes.

Referring specifically to the reflexes of the gastroenteric tract, Dr. Patrick O'Donnell and other expert roentgenoscopists have shown that, after the ingestion of the conventional bismuth meal, it takes approximately one hour and fifteen minutes for the stomach to void its contents but if the fifth dorsal spine is percussed (which opens the pylorus), the stomach voids the bismuth in one and one-half minutes.

Lebon and Aubourg presented before the *Société de Radiologie Médicale de Paris* comparative radiographs showing modifications of the large intestine after stimulation of different verterbral spines by my methods. They had ascertained upon administering castor oil, then a bismuth suspension, and finally examining the subject with the *x*-rays, that electrical stimulation of the right vagus in the neck caused contractions of the ascending colon, sufficiently marked to be plainly visible on the screen at each excitation of the nerve. Similar stimulation of the crural or sciatic nerves produced little or no change in the colon. Vigorous percussion of the seventh cervical spinous process caused the cecum to rise and the ascending colon to become broader; such effects were observed in all persons examined excepting one—a woman with marked enterospasm and constipation. Percussion of the dorsal spines had no effects on the colon until the lowest ones were reached; percussion of these, or of the lumbar spines, brought about contractions of the colon in all its divisions.

Desirous of determining whether one could similarly influence the appendix, the writer sought the assistance of expert radiologists and the results of his investigations may be briefly summarized as follows: In subjects having previously ingested bismuth or after enemas of barium sulphate, the appendix could be directly observed with the fluoroscope. It was noted that *percussion of the 10th dorsal spine emptied the appendix of its contents and concussion of the 1st lumbar spine caused it to refill.*

In rare instances, appendicitis is a local manifestation of a general infection (owing to implication of its lymphatic tissues). In the majority of instances, however, it is superinduced by the retention of feces, foreign bodies, and microorganisms which are discharged with difficulty.

At one time in his medical career, the writer was an ardent advocate of lavage for therapeutic purposes. Now the tube has passed into desuetude for this purpose and recourse is had to the more expeditious and less offensive method of percussing the fifth dorsal spine to evoke the pylorus reflex of dilatation.[1] The patient ingests several glasses of water after which, the fifth dorsal spine is gently percussed for one-half minute. This procedure is repeated several times just like in the conventional procedure of washing the stomach.

It occurred to the writer that evocation of the

appendix reflex of contraction might be of service in recurring appendicitis and the results achieved by many of his students and himself have justified this hope.

It would be puerile to anticipate any results in obliterated appendices and the method suggested should be limited to the chronic catarrhal forms of appendicitis.

The method in brief consists of percussion of the 10th dorsal spine: the daily *séance* should not exceed three minutes, and to avoid exhaustion of the reflexes the three minutes *séance* should occupy only one-half minute of treatment followed by one-half minute of rest. In other words, the three minutes treatment consists of one and one-half minutes of treatment and an equal period of rest. A like procedure is indicated in all the methods of spondylotherapy for eliciting the reflexes. A percussion hammer and pleximeter suffice for executing the method. If an apparatus is employed one yielding a blow and not vibration is indicated. The latter fact cannot be sufficiently emphasized and it is a disregard of this injunction which may bring the methods of spondylotherapy into disrepute. It suffices to say that the clinician elicits his reflexes by blows and not by vibration.

SOME OBSERVATIONS ON THE NATURE OF SHOCK.

By HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

Human life is destroyed through the operation of three agencies, shock, poison, and starvation. While these three destructive elements may combine to shorten or destroy life, they never unite to prolong or preserve it. Old age means sclerosis or hardening, which is but another term for progressive starvation. The rise and development of sarcoma afford a typical illustration at times of the union of these three elementary forces of destruction: the location of the growth may entail starvation through pure mechanical obstruction; degenerative changes may be accompanied by mixed infectious elements the absorption of which induces poisoning; and copious bleeding may terminate life almost instantly from shock.

Shock, as its influence involves the issues of human life, may be defined as any exhibition of force that disturbs or destroys the functions or tissues of the living organism. In a word, shock is violence, arising from any source, of any degree whatever, of sufficient power to exert an unfavorable influence upon the processes of life. Contrary to some false teaching arising from a misconception of scientific terms, shock has a definite pathology, regardless of whether or not the changes due to its influence leave a record in morbid anatomy. It must be borne in mind that the term pathology is abstract, and refers not to tissues but to processes, although the proper term pathological anatomy is often confounded with it. The very word shock instantly admits the existence of pathology, but not necessarily the confirmation or proof in the way of altered tissues.

The proper scientific comprehension of shock requires us to look beyond those pictures of physical violence, in which some of its great powers are so vividly illustrated, and well into those delicate and far-reaching effects that may not be properly assigned to any other cause. To see a human being struck by a rapidly moving locomotive and hurled through the air, to land a mass of mangled tissues, appeals so powerfully to our imaginative faculties that we take little note of what effect may have been produced upon some sensitive bystander, whose march to the grave begins then and there. One body is struck with tremendous violence and is shocked to instant death, whereas another body is also shocked by the mere sight of the disaster into a state of helpless and fatal invalidism. That sudden death may, and often does, result from a violent shock to the emotions is perfectly well known and is as freely admitted; but that the effects of shock may be prolonged over a period of years is just as true, but is not so well understood nor so frankly conceded. The matter is one of such importance in our every day practical attendance upon the sick that I purpose to submit some convincing illustrations of what may not altogether improperly be termed delayed or chronic shock.

During the early Nineties of the preceding century, I knew somewhat intimately a talented, energetic, and highly successful business man of 55 years. He was in the full prime of his vigorous powers of mind and body, abounding in advanced ideals and aggressive policies, full of that genial dignity of character that can praise without flattering, and reprove without wounding, a subordinate. I knew him to have been a man of the most correct physical and mental habits. He never touched alcohol in any form, and smoked a mild cigar only on rare occasions. One day he said, with a smile, "Buttermilk is my principal intoxicant, but once in a while I take a spree on coffee." On one occasion he escaped by the narrowest of margins a horrible death from burning, although he suffered not the slightest physical injury from the accident. From that time, however, his powers of mind and body declined in almost equal pace, until, a few years later, his whole being appeared to be dissolved in a cloud of timidity. A mind singularly keen and a will of peculiar strength were supplanted by whims of temper and vacillation of purpose. While I cannot in this place be more specific, it is the simple truth to say that this man's decline brought disaster and ultimate ruin upon an institution of national importance. At this time I do not doubt that his decline and death were as much due to the effects of shock as if he had fallen from his office window to the sidewalk below and had knocked his brains out in the impact.

Twenty years or more ago the official head of a large institution became the innocent victim of a domestic scandal aggravated by a social horror the precise nature of which cannot be repeated. Overwhelmed by a sense of shame and grief, he sank into

the depths of mental gloom and physical decay from which nothing could ever arouse him. The boundless sympathy of devoted friends and the immense resources of a powerful will were alike impotent in the face of a dark tragedy whose gloomy outlines could be effaced only by the total darkness of the grave. The darker pages of human history are filled with such instances.

Instances of persons "frightened out of their senses," or "frightened to death," are much too common to excite extended comment; they occur every day, in all climes and among all nationalities. But it ought to be well understood that shock to the emotions is capable of producing long-sustained and ultimately fatal alterations of tissue. It is no rare thing to learn of persons who "have not been quite right ever since" such and such an occurrence of a shocking character took place.

Nor must the prolonged and ultimately fatal effects of physical shock be ignored. The most celebrated editor of the Middle West, who passed away a generation ago, had undoubtedly been the victim of progressive cerebral sclerosis for years before his death; but the total wreck of his mental powers was clearly brought about through the effects of physical shock. As narrated by his biographer, the aged editor, laboring under some delusive "revelation" from a supposed "spirit," filled a large bathtub with ice-cold water and immersed his body in the chilling fluid, where he remained helpless for nearly an hour. According to the narrative of the biographer, "the shock destroyed the last particle of his intellect and left him idiotic." Instances of a similar character might be multiplied. A man of 29 years, of apparent vigorous health, had his left arm and forearm so seriously crushed in an accident that amputation became necessary. Perfect union followed the operation, yet the patient never recovered from the shock of the accident. Within a few months, acting upon the advice of his family physician, he journeyed to the more genial climate of the southwest, but died quickly from acute nephritis of which there had been no previous evidences.

The careful and thoughtful student of the phenomena of shock will soon learn that there are many facts and incidents connected with human life that are insoluble alike in the laboratory and upon the operating table. Cancer of the uterus, so well fixed in our minds as being associated with spontaneous bleeding, does not appear during the period between fifteen and forty, when the uterus is usually and periodically a far greater center of vascular activity than it is either before or after that period of life. Masses of scar tissue imbedded in the uterine cervix cannot be viewed otherwise than as a source of possible mischief, yet cancer does not arise from scar tissue. I have heard well-informed physicians express a belief that "a purulent uterine discharge will often cause cancer of the cervix," yet it is certain that the student of pathology will search long and patiently before he will discover a case of urethral cancer in the male subject due to such a discharge.

In no case demanding surgical interference must we lose sight of the interdependence of the various bodily structures, nor of the peculiar and unaccountable freaks of tissue for which no acceptable rational cause can ever be assigned. It is certain that we cannot observe too closely, study too carefully, and report too candidly, all the known phenomena of the intricate machinery whose care and restoration when disordered depend so largely upon our individual efforts.

Medicolegal Notes.

Heat Prostration an Accident.—In a proceeding for compensation under the Pennsylvania Workmen's Compensation Act, the rule is affirmed that the term "personal injury" in that act is confined to injuries of accidental origin and such diseases as naturally result therefrom, and must be held to include any form of bodily harm or incapacity accidentally caused by either external violence or physical force. A stroke by lightning, a stroke from the direct rays of the sun, a heat stroke, or heat prostration, are untoward unexpected mishaps, and accidental injuries within the meaning of the act. It is immaterial whether the heat prostration is produced by artificial heat, or by the natural heat of the sun, directly or through the heated atmosphere, if the exhaustion comes from heat in the course of employment. Ordinary or occupational diseases developed during the course of the employment are not within the contemplation of the statute. The court held that an employee, overcome by heat while working at his employer's lunch counter on a hot day, and who died within two hours, suffered an "accidental injury in the course of his employment" within the act.—Lane v. Horn & Hardart Baking Co., Pennsylvania Supreme Court, 104 Atl. 615.

Evidence as to Impersonation of Insurance Applicant.—In an action on a life policy, where the defense was impersonation of the applicant before the medical examiner and false statements as to health, a doctor who attended the applicant prior to the issuance of the policy testified that at the time of his examinations he found her suffering from serious heart trouble. He was then asked, "Was her condition at that time such that a doctor, using ordinary care in making a medical examination, would have discovered this heart murmur that you speak of?" It was held that the evidence sought to be elicited by this question was relevant, as bearing upon the question whether or not the deceased was the woman examined.—Suravity v. Prudential Ins. Co., Pennsylvania Supreme Court, 104 Atl. 754.

Necessity for Demand for Autopsy.—In a proceeding for compensation for the death of a workman from strangulation of the intestines found by the Industrial Board to have been caused by hernia resulting from a strain while at work, it was contended that the applicants for compensation were not entitled to an award because they refused the employers the benefits of an autopsy, and that such examination of the body was necessary to determine the cause of death. There was conflict in the evidence as to the necessity for the autopsy, and also on the question of the time of its demand. Whether the refusal of a demand for an autopsy, made after the burial of the workman, will in any case deprive his dependents of their right to compensation under the Workmen's Compensation Act the Indiana Appellate Court did not determine. A demand therefore must, however, be made at a reasonable time and place. The evidence being conflicting the finding of the Industrial Board on the question was conclusive on the appellate court.—Vonnegut Hardware Co. v. Rose (Ind.), 120 N. E. 608.

Expert Evidence—Different Schools of Medicine.—In an action against a homeopathic physician for alleged malpractice the Iowa Supreme Court held that an "allopathic" physician should not have been allowed to say that the patient should have had some medicine producing a physiological effect. In calling a physician one is presumed to elect that the treatment shall be according to the school to which the physician belongs, and his care cannot be measured by the sort of treatment a physician of another school would have given. It was held that in such an action an "allopathic" physician could testify as to what the customary treatment in such cases in that locality was, but could not make comparison with the treatment given by the defendant.—Van Sickle v. Doolittle (Iowa), 169 N. W. 141.

Military Medicine.

A New Method of Gunshot Wound Treatment.—Dr. Robert Donaldson, in a thesis published in *The Edinburgh Medical Journal* for January, 1919, deals with a new method of wound treatment evolved by him. The thesis in fact is an account of his discovery or isolation of a spore-bearing anaerobe from wounds undergoing successful salt pack treatment, with a description of the manner in which this anaerobe acts and a comparison between the healing properties and those of other methods in vogue in the treatment of infected wounds. The organism he named the "Reading bacillus." It is described as a spore-bearing anaerobe possessing strong proteolytic properties. Its behavior in a medium of cooked meat at once suggested to Donaldson the possible rôle it played in septic wounds, viz., that it broke down or hydrolyzed dead protein tissue and by so doing destroyed pabulum on which pathogenic organisms flourished. Given suitable conditions for active growth and proliferation, it probably did in the dead tissues of the wound what it obviously did *in vitro*, viz., it digested them. According to Donaldson, the superiority of the Reading bacillus in the treatment of septic wounds is that it is able to dissect away, as it were, not only the macroscopically but also the microscopically dead material in a way that no surgeon's knife ever can, and accomplishes this without at the same time inflicting any fresh trauma. The Reading bacillus acts, in short, as a bacteriological scalpel.

The technique of the Donaldson method of treatment is as follows: First it must be laid down as an axiom that all gunshot wounds should be freely opened up and thoroughly explored. Every pocket should be laid open, so that the subsequent packing shall come directly into contact with all parts of the wound surface. As such wounds are frequently of an irregular and burrowing character to do so efficiently will call for ingenuity on the part of the surgeon. All foreign bodies ought, if possible, to be removed and care should be taken to ensure that no adjacent collection of pus has been missed. The interior of the wound is now irrigated with very hot sterile water or saline solution to wash away obvious pus or blood and to assist in checking capillary oozing. By means of a pipette the whole surface of the wound is liberally sown with a living culture of the Reading bacillus, commencing with the deeper parts. The cultures which Donaldson is in the habit of using have been grown in cooked meat broth. It is perhaps an advantage for some reasons to use a three-day-old culture, but one many months old will serve equally well. Immediately after sowing, the packs, whether of salt or sphagnum moss slightly moistened with sterile water or saline, are introduced and so arranged that they fill the wound cavity completely, leaving only the tails of the bag projecting. In some cases it may be found more convenient to distribute the culture over various parts of the wound in turn, packing each section as it is sown. When all the packs are *in situ*, several layers of plain sterile gauze, moistened with sterile water or saline, are laid over the packing, in such a way that they overlap the edges of the wound. The whole is then enveloped in thick layers of cotton wool and firmly bandaged. It is an additional advantage if some form of splint can be applied to aid in steadying the part. Just how long the packs require to be left in will probably depend on the size of the wound and the amount of dead tissue present, but in human beings the period ought probably to be at least seven to nine days. At the end of this time the packing may be removed without the aid of an anesthetic. After gently detaching the board-like upper dressings, the actual packing, be it salt or moss, comes out easily en masse, bathed, as a rule, in bright yellow pus, from which the Reading bacillus can be recovered if desired. The wound surfaces are then irrigated with eusol or with warm sterile saline to wash away all clinging pus and débris, after which the wound will be found, as a rule, perfectly clean.

Donaldson summarizes his article as follows: (1) He gives the name of the biological method to this new treatment of gunshot wounds to distinguish it from the antiseptic, the physiological and the surgical. (2) It is based on revised ideas which Donaldson has found regarding the relative importance to be attached to the various factors which prevent wound healing. (3) The new method depends on the introduction to the wound of a spore-bearing anaerobe of a saprophytic character belonging to the proteolytic group of organisms. (4) It is non-pathogenic when introduced into gunshot wounds and in the course of its activities does not give rise to toxic products injurious to the patient. (5) The Reading bacillus is probably to be found in the majority of gunshot wounds, but is unable to exert its beneficial action except where anaerobic conditions obtain. Hence the reason for its appearance in salt packed wounds. (6) The biological method is not synonymous, however, with the salt pack method of treatment, although the latter is dependent upon the Reading bacillus for success. Salt is not only not essential but may actually impede proliferation of the organism. Spagnum moss or anything indeed that will secure anaerobic conditions in the wound may be substituted for the salt packs with equally good results. (7) All the methods of wound treatment hitherto in use have been directed almost solely toward destruction of the infecting flora and arrest of proteolysis in the wound. Their relative efficiency actually depends, however, on their influence if any, on the necrotic tissue present. (8) Special emphasis is laid on the great danger resulting from dead and damaged tissue in a wound, and Donaldson has attempted to show that this should be the chief point to which treatment should be directed. (9) The antiseptic and physiological methods fail to realize this, and consequently find themselves in process of being supplanted by the surgical method of wound excision. The superiority of the latter over the two first named depends not so much on the speedy removal of infective organisms, for which purpose it was originally intended, but on the fact that it removes a large part of the dead

tissue as well. (10) The surgical method, however, is not always anatomically possible, may fail to remove all the dead tissue present, is a mutilating form of treatment, and by its very nature inflicts a fresh trauma leaving a zone of death behind to form a base for fresh organismal activity. (11) The biological method, on the other hand, belongs to quite a different category, inasmuch as its avowed object is to hasten proteolysis. (12) The Reading bacillus has a twofold action. It not only disintegrates the dead tissue upon which pathogenic organisms live and from which as a base they are able to keep up a continual bombardment of the patient's body by means of toxic degradation products, but to judge from Donaldson's experimental work, it is probably able to destroy these toxins so that they are no longer absorbed. (12) The former action brings about a local improvement in the wound which is rapidly, automatically, and easily freed from all necrotic material, while the latter puts a stop to continued toxemia, as is proved by the rapid constitutional improvement which takes place. Pending removal of the supply base by the Reading bacillus, the further absorption of toxins by the patient is prevented. (13) Both results are achieved by reason of a proteolysis action produced by the Reading organism. This enzyme acts as a living-catalyst which is able to hydrolyze not only dead protein but also the toxic degradation products of other organisms. Once introduced into the wound and given suitable conditions for development, the Reading bacillus will go on forming enzymes as long as there is any dead protein to hydrolyze. For these reasons, therefore, it differs from all other known methods of wound treatment hitherto employed, and while opening up new possibilities for the more efficient treatment of toxic absorption in general, raises other side issues of considerable importance. It becomes, in short, a problem in colloid chemistry. (14) The advantages claimed for it include simplicity of application, the avoidance of daily dressing and daily disturbance of the wound, the rapidity with which a sloughy wound becomes a healthy granulating surface, the absence of secondary hemorrhage, together with the remarkable and speedy improvement which takes place in the general condition of the patient. All of which means considerable curtailment of the time generally spent by a wounded man in hospital.

New Figures on France's War Losses.—New figures on the French war losses have been given out by the French Foreign Office which bring the number of French dead to more than 1,600,000. The new compilation shows that more than 300,000 colonials died in the fighting, the greater part of this loss having been borne by the Algerians. This report is interesting in that it notes the contribution to casualties by classes. The French nobility suffered greater losses than any other classes. Next to the nobility, the professional classes were the greatest sufferers, the percentage of artists, physicians, dentists, architects, writers, sculptors, musicians, poets, and actors being a little over 9 per cent. The financial and industrial classes contributed least to the nation's casualties, though a large percentage of them were in the industrial army behind the lines.

Test Air Ship Ambulance.—Lieut. David Grey of the Royal Air Forces, a convalescent aviator, who was wounded overseas, was recently transported from the Naval Aerial Station at Far Rockaway, L. I., to St. Luke's Hospital, Manhattan, by airplane. The airplane made the trip from Far Rockaway to the foot of Ninety-sixth Street in sixteen minutes, where the patient was transferred to a motor ambulance, which covered the remainder of the distance to the hospital. The patient was bound to the stretcher, which was then fastened in the airplane. Further tests along these lines are to be made, with a view to ascertaining the practicability of an ambulance air service during actual warfare.

Women Physicians Decorated.—Dr. M. Louis Hurrell of Rochester, N. Y., director of the American Women's Hospital at Luzanoy, France, and several physicians and nurses on her staff, have been decorated by the French Government for their work in stamping out typhoid fever in certain cantons of the Seine, the Marne, and the Aisne.

Army Officers Banquet Their Chief.—Officers of the Hospital Division of the Surgeon General's office tendered a farewell dinner at the Shoreham Hotel on March 6, in honor of Col. Winfred H. Smith, who is retiring as chief of the Hospital Division, and to Col. L. B. Baldwin, in charge of the administration of the Hospital Division.

Deaths in the Service.—Lieut. HENRY REUBEN WESTON, M. C., U. S. Army, a graduate of New York University and Bellevue Hospital Medical College, in 1903, died on November 27, 1918, of gangrene of the lungs, while on duty in the Philippine Islands, at the age of 40 years. He was a member of the Association of Military Surgeons of the United States.

Lieut. JOHN AWVILL PENNINGTON, M.C., U. S. Army, of New York City, a graduate of the University of Tennessee, Nashville, in 1918, died from pneumonia, on October 4, aged 26 years.

Lieut. LEO CASSIUS MILLER, M. C., U. S. Army, of Champaign, Ill., a graduate of the University of Illinois, Chicago, in 1906, after serving at Camp Greenleaf, Ga., and at the Embarkation Hospital at Camp Stewart, Va., died at his home of pneumonia, following influenza, on December 14, aged 36 years.

Lieut. DAVID HALSEY PARLIAMENT, M. C., U. S. Army, of Covington, Ga., a graduate of the Georgia College of Eclectic Medicine, Atlanta, in 1913, and professor of chemistry and urinalysis in his alma mater, died of pneumonia at Camp Dix, N. J., October 2, aged 35 years.

Capt. ELIAS CAMERON CRUMMEY, M. C., U. S. Army, of Jesup, Ga., a graduate of the Atlanta College of Physicians and Surgeons, in 1905, died from bronchopneumonia, while on duty at Camp Wadsworth, Spartansburg, S. C., on November 26, aged 47 years. He was secretary of the Wayne County Medical Society from 1915 to 1917.

Lieut. BLANEY WILLIAM COX, M. C., U. S. Army, of Goldesboro, N. C., a graduate of the North Carolina Medical College, Charlotte, in 1915, died from pneumonia following influenza, on October 8, aged 30 years.

THE TREATMENT OF WAR WOUNDS.

A SPECIAL number of the *U. S. Naval Medical Bulletin*, issued recently, contains a report on medical and surgical developments of the war by William Seaman Bainbridge, Lieutenant Commander, M. C., U. S. N. R. F. In view of the wide differences of opinion which exist even now as to the relative value of antisepsis and asepsis in the treatment of infected wounds, it is instructive to note what the author says on this subject. He relates that meeting Professor Kocher late in September, 1915, this celebrated authority said to him, "The great lesson of the war so far is, back to antiseptic surgery. Asepsis is not enough." In contrast to this statement, three years later Major A. L. Lockwood, R. A. M. C., who had one of the largest experiences in acute war surgery in the present conflict, said, "One of the greatest lessons of the war is that aseptic surgery and not antiseptic surgery should be practised, the former in all cases, the latter associated with it in selected cases." Bainbridge, after going from hospital to hospital and station to station, and hearing each of these many methods acclaimed or criticized, became convinced that the obtaining of satisfactory results depends far more upon the surgeon himself than upon the agent which he employs. He therefore holds the view that the lesson to be learned from all this diversity of opinion is that those who are to be given charge of this surgical work should have, first, a thorough knowledge of surgery; second, sufficient experience to give them an adequate technique; and third, the necessary judgment to select and employ such of these methods or agents as may seem best for the particular case at the given time.

From the purely therapeutic viewpoint the surgery of wounds in the present war may be grouped under fairly approximate chronological headings, as follows: (1) The period of ordinary antiseptic agents; second half of 1914 and first half of 1915. (2) The period of wound drainage combined with antiseptics, 1915. (3) Introduction of hypochlorites; later in 1915. (4) Evolution of the Carrel technique of intermittent wound instillation; early in 1916. (5) Ascendency of bipp method. (6) Period of approximately equal use of the Morison and Carrel methods; 1916-1917. (7) Prominence of flavine and colored wound pastes, such as brilliant green; 1917. (8) Progressive general adoption of wound incision method, which had its beginnings early in 1916; late in 1917. (9) Period of primary wound suture, immediate or delayed; 1917-1918. (10) Period of attempted selection, adaptation and standardization; late 1918.

Of the various methods described in this exhaustive and lucidly written report, some, as wound suture, the Carrel-Dakin method, and bipp, have been so thoroughly dealt with already that it would be tiresome to recapitulate; also the salt pack method has been explained on several occasions.

With regard to flavine, it is noted that it is preferred by Sir Anthony Bowlby, as a dressing with sterilized gauze, after excision has been done, before suture, for the reason that it has no toxic or irritating qualities, and the gauze soaked in it, and kept moist by jaconet and absorbent wool, does not stick to the tissues, and leaves a good surface for suture. Of course, the lymphagogic agents are described.

According to Bainbridge, heliotherapy or sunlight treatment of war wounds deserves to be more extensively employed as a physiological curative method, the routine adoption of which is urged by Dr. M. Cazin as a measure capable in many cases of greatly abridging the duration of the treatment of war wounds and essentially reducing the number of war invalids. In the experience of Cazin, atonic and indolent wounds, on exposure to the sun, became regularly covered with a layer of healthy granulations. Excellent results were obtained in infected fractures, and in several cases where the bony lesions were such as to endanger the preservation of the limb, heliotherapy led to complete consolidation and perfect recovery.

Attention is drawn to phenolization and embalming of war wounds advocated and practised by Dr. L. Mencière, the Médecin-Chef of the Hôpital de la Compassion in Rheims in 1916. Mencière recommends this method on the basis of favorable experience in wound treatment, including the gravest articular traumatisms and especially in the treatment of gas gangrene. The performance of primary suture, immediate or delayed, is often made possible by the employment of this procedure.

Bainbridge is in favor of oxygenation of infected wounds and points out that oxygen, far from damaging the cells, has been shown to stimulate cellular activity, to activate phayocytosis, and to aid all defensive reactions such as diapedesis and secretions. Aside from its effect on anaerobes, it has no destructive action upon microorganisms, but by stimulating the activity of the natural defensive forces furthers the power of resistance and in this way becomes a valuable physiological assistant in the fight against infection, upon the winning of which depends the success of surgery in general and war surgery in particular.

A portion of the *Bulletin* of considerable interest is that which is concerned with the treatment of war wounds by Germans. In the summer and fall

of 1915 Dr. Bainbridge made a fairly extensive tour of the hospitals in Germany and was much impressed with the efficiency of the ambulance and hospital organization. Perhaps the feature of this organization which made a special impression upon him was the great attention paid to physical therapy. Before the war German medical men had made great progress in this direction, and in many of the hospitals departments of physical therapy had been established. At that time in Germany no one method of controlling wound infection had been adopted. Although irrigation with dilute antiseptic solutions was employed by German surgeons, opinions differed widely as to the value of antiseptic agents. Irrigation with hydrogen peroxide has been extensively used in their military hospitals and is claimed to be especially efficacious in the treatment of infected fractures.

In opposition to the antiseptic method of wound treatment, and in analogy with the physiological lymphagogic method indorsed by Sir Almroth Wright, some German writers on early wound treatment at the front have proposed the use of nitric salts, which on coming into contact with organic substances are at once reduced to nitrous salts. The object aimed at is to increase the hyperemia in these invariably infected wounds and to produce a free flow of lymph. It is pointed out that Germany has given considerable attention to the after-care of the wounded soldier, with a view to returning him to the ranks if possible, or if he must be sent back to civil life, making him self-supporting and not a burden to the community.

This special number of the *Naval Bulletin* is profusely illustrated by excellent photographs and provides a mine of information as regards surgery, medicine, and physical therapy relating to the war.

THE COMATOSE FORMS OF INFLUENZA.

It is interesting to see how a medical phenomenon may sometimes exist for a long time unnoticed until suddenly it is brought to public or professional attention by some more or less trivial incident, and then everyone says, "why, of course." The present newspaper talk of "sleeping sickness" is an instance. Some one discovered a number of cases of the comatose form of influenza in Chicago and at once cases were found to exist in New York, Washington, and other cities. Inquiry among practitioners generally would doubtless reveal the fact that cases with comatose symptoms had occurred every now and then all through the course of the influenza epidemic. They are observed in nearly every epidemic of this disease and are as truly influenza as are the cases with pulmonary, gastric, or cardiac symptoms. Ditmar Finkler, in his incomparable treatise on influenza published in the "Twentieth Century Practice of Medicine," in 1898, and still the most comprehensive and best work on this subject in the English language, describes this form as follows:

We may also mention the so-called comatose form of influenza. Occasionally in the beginning or during the course of an influenza we may see a marked somnolence, increasing perhaps to coma, without any other cerebral symptoms. Friedrich Müller in Pforzheim observed a case of this form of coma which lasted fourteen days. In the spring of 1890 the newspapers were filled with reports that a new disease, called noma or sleeping sickness, had broken out in some parts of Italy. This disease presented symptoms which were similar to the observations of Krannhals, in which the clinical picture resembled that of a cerebrospinal meningitis which was not yet fully developed. According to the description of these cases of somnolence, appearing in an epidemic form, the greatest probability is that they were cases of influenza in which these comatose conditions were pronounced, as they may also be in hysteria. That they had accumulated in certain parts of the world need not seem more remarkable to us than the fact, already frequently mentioned, that other forms of influenza have shown an inclination to make their appearance in a cumulative manner in certain localities at a certain time. Leichtenstern insists that this noma should be clearly distinguished from cerebrospinal meningitis, especially as pneumonia was a frequent complication.

Finkler also describes the encephalitic form of influenza which is a much more serious condition, often ending fatally. It is marked by more or less pronounced paralysis—mono- or paraplegia—and often by grave cerebral symptoms such as coma, convulsions, or delirium. The paralysis is not constant, however, for if the encephalitic foci do not affect the motor centers and paths, signs of motor irritation and paralysis will be absent, high fever, unconsciousness, and coma being the only symptoms. These forms were first noted during the epidemic of 1889-92, no allusion to them being found in the literature of previous epidemics.

The history of medicine is a subject deserving of much more assiduous study than it receives to-day. If it were made a part of the curriculum of every medical college, the future practitioner would be saved from the commission of many errors and the science of medicine would be advanced mightily.

THE MENTAL STATUS AS AN ETIOLOGICAL FACTOR IN HYSTERO-TRAUMATISM.

The mental status of the subject is of capital importance in the etiology of hystero-traumatism. Traumatic hysteria is frequently met with in hysterical subjects as well as in individuals who had offered no evidence of the neurosis until the receipt of the trauma, although they were strongly predisposed to it by their familial antecedents. Finally, although exceptionally, the neurosis develops after trauma in subjects absolutely free from any neurotic stigmata. The exact part played by trauma in hystero-traumatic accidents may be summed up as follows: The trauma does not create hysteria and usually does not cause the hysterical accidents in hysterics. The injury has as an effect only to disturb the nervous system of the subject, thus rendering him more impressionable and, consequently, more sensitive to suggestion. In the hystero-traumatic accident, suggestion or autosuggestion is the one great factor in the creation of the phenomenon.

As Forgue and Jeanbrau have pointed out in reference to Charcot's theory of the pathogenesis of hysteria, a dangerous and unforeseen accident provokes two effects, namely, a physical and a psychical shock. The former suspends the functions of the limb which remains painful, benumbed, and impotent for several days. The fright and anguish, occasionally a retrospective sentiment of terror, felt by the patient when he awakens after having lost consciousness, provokes a psychical shock which suddenly disturbs the cerebral functions, suspends perception, and as a consequence the faculty of controlling the sensations starting from the injured region. Briefly, for Charcot and his school, hystero-traumatism consists in a traumatic suggestion in a latent hysteric. This suggestion causes the subject to forget movements or sensations or both (hemiplegia with hemianesthesia) in a given region.

The late Prof. Grasset applied his doctrine of inferior psychism to the pathogenesis of hystero-traumatism and his theory would seem to throw a perfectly clear light on this much mooted question. As is known, Pierre Janet distinguishes two kinds of psychic functions, the one superior, comprising the consciousness or responsible ego, which has no known cortical localization; the other termed the inferior or subconscious psychism, comprising the cortical centers of hearing, sight, speech, writing, general sensibility (tactile center), and coordinated movements, as well as their tracts of association. The inferior psychism, whose centers and ways of communication may be figured by a polygon, carries out its functions automatically without the interference of consciousness, and is placed ideally in an O-center communicating with all the centers of the polygon. Thus, according to Grasset, when writing a sentence we create the idea in the O-center and direct the movements of the hand for the formation of the letters and words from the polygon in a way that habit has rendered unconscious and automatic. During sleep the polygonal life is not suppressed, only the consciousness sleeps.

Now, if under the influence of a sharp emotion, a psychical shock, the consciousness (O-center) is suddenly annihilated at the same time that a region of the body is injured, the image of the lesion may become fixed in the polygon and when consciousness returns the patient may no longer be able to move the injured limb. He has forgotten his movements unless, as in an arthropathy, the entire region is the seat of a severe pain which is increased by the slightest contact. The phenomenon of hystero-traumatism is established and it can readily be conceived that the longer it has been present the greater will be the difficulty of doing away with it. However, a trauma similar in nature to that which produced the hystero-traumatism may quickly unmake it. Consequently, by Grasset's ingenious theory can be explained not only the hystero-traumatism itself, but likewise its evolution, sudden recovery under some given influence or its relapse in circumstances quite independent of an accident.

INFANT WELFARE IN GERMANY DURING THE WAR.

In all Europe, and, of course, more especially in those countries engaged in war, infants and children have suffered severely, and this constitutes one of the most important after-war problems. Conditions in Germany during the war have been largely veiled in obscurity, or camouflaged, as they seemed to suit military exigencies or the wishes of the ruling caste. The reports from Germany itself in the past four years have been so contradictory that no reliance whatever could be placed on them, and even now it is very difficult to arrive at the truth. When the war was going on it was usually declared that infants and children were not very adversely affected by the blockade; but now that Germany is beaten, and it is the policy of the country to appeal to the sympathies of the world at large, it is asseverated that hundreds of thousands of infants and children were wiped out by Great Britain's cruel blockade. The truth appears, as is generally the case, to lie between these two extreme statements, and probably Germany suffered in infant mortality to about the same extent as the other big warring countries, and less than the smaller countries, as Belgium, Poland, Serbia, and Roumania. It must always be borne in mind that for a considerable part of the war the blockade was notoriously inadequate.

The real facts of the condition of infants in Germany while the war was in progress are beginning to leak out. Recently an instructive summary concerning infant welfare in Germany during the war has been given in a report prepared by the intelligence department of the British Local Government Board in 1918, which has just been published. The summary was reproduced in Public Health Reports for February 14, 1919.

The most striking feature of the information set down in the document is the heavy decrease shown in the number of births. Some 40 per cent. fewer babies were born in 1916 than in 1913. On the whole, the infantile death rate was well kept down. According to the British report, the reduction in the rate was due partly to the special measures taken and partly also because of the cool summers. The chief measure adopted in Germany to promote infant welfare during the war was the distribution of imperial maternity grants. One of these grants is given only to women who feed their babies at the breast, the encouragement of breast feeding being regarded as one of the most powerful agencies for furthering infant welfare.

Illegitimacy increased greatly in Germany in the past few years. The proportion of illegitimate births in the entire German Empire is between 9 and 10 per cent., and in certain districts the rate is much higher. The care of foster children was interfered with by the war on account of the mobilization of medical men appointed to look after them. However, when affairs had become settled on a war basis, illegitimate children were cared

for better than ever before. Foster children and children whose mothers were working outside were taken care of both in homes and in institutions. It is claimed by those concerned in the welfare of infants and young children that these are better cared for by trained and supervised workers in crêches or infants' homes than in the houses of foster mothers, especially in view of the difficult food conditions that must still prevail for a considerable time.

A discussion of the subject of infant welfare in Germany recalls the recent request of workers in this field to the British Government for permission to import from England a supply of rubber nipples for nursing bottles. The petitioners urged that this was imperatively necessary to save the lives of thousands of infants, and to clinch the point by an unanswerable argument they added that if this request was refused, by 1933 there would be no men fit for army service. The naiveté of this statement is delicious, and is on a par with many other manifestations of the utter humorlessness of Teutonic efficiency. With minds set on the goal, they are absolutely blind and deaf to all side issues.

Bacteriological Findings in Epidemic Influenza.

The cause of influenza remains obscure, and the investigations of bacteriologists appear to have been almost barren of results so far as deciding its origin is concerned. The Pfeiffer bacillus has largely fallen into disrepute as a causative agent, and bacteriologically we are as far from the solution of the influenza problem as ever. Dr. S. E. Howard of the medical clinic of the Johns Hopkins Hospital records in the *Johns Hopkins Bulletin*, January, 1919, some investigations made by him with the object of tracking the causative germ of influenza to its lair. He confesses that he is unable to do so, and states that he and his coworkers feel conscious that none of the organisms isolated by them may be regarded as the cause of epidemic influenza. Their results, together with the results reached by the majority of European investigators, convince them that the *B. influenzæ* of Pfeiffer is merely a secondary invader, although in some localities it may be a frequent cause of terminal bronchopneumonia. The other organisms isolated may also be regarded either as normal inhabitants of the mouth or as secondary invaders. The conclusion arrived at by Howard and fellow workers is that the primary cause of epidemic influenza is still unknown. With this conclusion most investigators will probably sorrowfully agree.

Influenza and Epilepsy.

The epileptic has always shown considerable natural immunity to infections of certain kinds, and his wounds often show a surprising readiness to heal, even when he is under the influence of bromine. It will therefore be of interest to note how he reacts to grippe, and Maillard and Brume of the Bicêtre, Paris, have reported the interrelations of the two maladies in *La Presse Médicale* for February 10. The pandemic passed over the hospital region in two waves, in June and October respectively. The first fact established was the severity of the course of the grippe in the epileptics, while the second was the verification of the old observation that severe infections diminish the number of seizures. Third, the first wave of grippe immunized the victims against the ravages of the second wave. During the course of the grippe all of the patients remained almost free from epilepsy. Thus, in patients who showed collectively 105 seizures the total was reduced to 14 during the corresponding period. The convulsions returned with their old frequency after defervescence. In regard to type and mortality, of 63 epileptics attacked, 22 presented simple and 41 complicated cases, all but one of which were pulmonary. The deaths numbered 32, or just over 50 per cent. In all but 2 of 32 the cause was either croupous pneumonia, bronchopneumonia, or pulmonary edema.

News of the Week.

Medical Aeronautic Congress.—The first interallied medical aeronautic congress opened in Rome on March 11. Its object is the study of medical problems arising from aviation. Resolutions dealing with physical and psychological tests applicable to applicants for pilot's licenses, the control of flights to high altitudes, and the use of oxygen by aviators, were presented. It was decided to form a permanent committee to present the views of the medical profession in matters pertaining to aviation. Dr. L. G. Roundtree of Minneapolis represented the United States.

High Mortality of German Babies.—Herr von Braun, Under Secretary of State, has recently given out figures showing the great increase in mortality among infants under a year old for the last three months of 1918. The deaths during this quarter amounted to 6,142, as compared with 4,176 for the same period of 1917. Medical experts attribute the increase entirely to the inability of the mothers to nurse children on their scanty diet, or to keep them alive on the one quart of milk of poor quality to which the milk ration of infants has been reduced. During the first three years of the war the infant mortality of Germany was decreased as compared with peace years. This was attributed to the tendency of mothers to nurse their children during the years of war privation. For the year 1917 the deaths of children from one to five years of age was 49 per cent. higher than in the last peace year—1913—and the deaths of children from five to fifteen years of age 55 per cent. higher. It is said that unless immediate and adequate relief in the way of food comes, the rising generation is condemned either to death or weakened maturity.

New York's Baby Death Rate Low.—Statistics issued recently by the New York Health Department show that in 1918 New York had the lowest infant mortality rate of any of the ten largest cities of the United States, and the second lowest ever recorded in the history of the city. New York's lowest infant death rate was 88.8 for 1917, while the 1918 ratio was 91.7. St. Louis ranked second with a rate of 94.4, while Baltimore was last with an infant death rate of 147.7. The Chicago death rate for infants was 131.3. The Health Department con-

siders this showing as exceedingly gratifying in view of the war, with its resultant economic conditions, and the influenza epidemic, which carried off many young mothers and deprived their children of care and nourishment.

New City Hospital for New York.—At a mass meeting of Washington Heights physicians, held on March 10, the temporary committee, called the Washington Heights Physicians' Campaign Committee for a City Hospital, was made a permanent organization, called the Washington Heights Physicians' League. The purpose of this organization is to secure a hospital for this section of the city. It is said that the hospital is practically assured, and a committee on site will soon be appointed. Dr. M. Joseph Mandelbaum is president of the league.

Brooklyn Diagnostic Institute.—An institution has been opened at 867 St. Marks Avenue, Brooklyn, N. Y., which has as its sole purpose to prosecute for the clinician such diagnostic investigations as are necessary in order to unerringly interpret all the morbid phenomena of a given case and to pursue a rational course of treatment. The directorate announces that the facilities of this institution for chemical, bacteriological, roentgenological, and allied research for the active practitioner are unsurpassed. Dr. Jacob Gutman is at the head of the institute, Dr. Max Kahn is the director of the biochemical laboratories, and Dr. I. Seth Hirsch is director of the roentgenological department.

Dr. Julieta Lanteri de Renshaw is a candidate for the Chamber of Deputies of the Argentine Republic. She is the first woman candidate for Parliament in the history of Argentina.

Dr. Alice Hamilton of Chicago has been elected to the position of assistant professor of industrial medicine in the Harvard University Medical School. She is the first woman to be elected to the Harvard University Faculty.

The Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases will hold a stated meeting on Tuesday evening, March 25 at the dispensary, 41 East 123d Street. Dr. Joseph Roth will send a paper on "Bone Lesions" and Dr. Howard Lilienthal will relate his "Personal Experiences with Surgery in the American Expeditionary Forces."

In Aid of Crippled Soldiers.—A meeting to further reconstruction work for those crippled in the war will be held at the Hippodrome on Sunday, March 26. A number of addresses will be made and there will be a chorus of 3,000 voices. Tickets may be obtained from the N. Y. County Chapter of the American Red Cross, 389 Fifth Avenue.

Booth Memorial Hospital.—The Booth Memorial Hospital on Stuyvesant Square, New York City, has recently been opened under the joint auspices of the Salvation Army and the American Red Cross. Its establishment marks the enlargement of an important phase of the war work which will probably continue during the coming year, namely, the giving of medical and surgical care to the families of soldiers, sailors, and marines, and in many instances, as demobilization continues, to the men themselves. This institution provides a kind of hospital service which the city has lacked hitherto—private rooms at a moderate cost. A large share of this part of the work is being done by the Salvation Army. The Red Cross conducts a medical station in connection with the hospital, which cares for selected cases and gives special attention to maternity cases and infant welfare work.

New York Hospital Asks for Help.—The New York Hospital, for the first time since its organization, 140 years ago, is making an appeal to the public for funds to make good a deficit of $100,000 incurred last year. In addition to its main hospital in West Sixteenth Street, the institution operates the Hudson Street Hospital and the Campbell Cottages and a hospital at Bloomingdale. The combined hospitals have treated 1,700,000 patients, and during the war maintained a fully equipped base hospital at Chateau Roux.

Pennsylvania State Board of Health.—Dr. S. Leon Gans of Philadelphia has been appointed chief of the State Genitourinary Dispensaries; Dr. John Laird of Reading chief of the laboratory dispensaries, and Dr. Howard L. Hull chief medical inspector.

Obituary Notes.—Dr. William Robert Arlington Carley of Brooklyn, N. Y., died in the Long Island College Hospital, following an operation, on March 11, aged 55 years. He was a graduate of Bellevue Hospital Medcial College, in 1888, and a member of the staffs of the Long Island Medical College Hospital, Bethany Deaconess Hospital, and the Brooklyn Hospital. He was a member of the Associated Physicians of Long Island and the Kings County Medical Society.

Dr. Alfred Whitehead died after a long illness at his home in Baltimore, on February 27, aged 70 years. He was a graduate of Queen's Hospital and the Royal College of Surgery, London, in 1871. He came to this country in 1882 and soon afterward became professor of children's diseases in the Baltimore School of Medicine. He later became professor in anatomical and clinical surgery at the same institution. He was a member of the American Medical Assocation, the Medical and Chirurgical Faculty of Maryland, and the Baltimore Medical and Surgical Society.

Dr. Edgar L. Griffin of Atlanta, Ga., died from the result of injuries received in an automobile collision on March 3. He was a graduate of the Southern Medical College, in 1894, and was 48 years of age at the time of his death. Dr. Griffin was recently designated by Surgeon General Blue to assist in combating the epidemic of influenza in Georgia.

Dr. William Shackelford died at his home in Dalles, Ore., on February 21, at the age of 80 years. He was a graduate of Jefferson Medical College in 1859, and served as surgeon in the Northern Army throughout the Civil War. He served several terms on the City Council of Dalles, and until recently served as city health officer.

Dr. Joseph Clinton Beard, a graduate of the New Orleans School of Medicine in 1861, and a graduate of the University of Paris, died at his home in New Orleans on March 3, aged 90 years. He served during the Civil War as a military surgeon in the Confederate Army, being on the personal staff of General Beauregard. For many years he was city physician, and also held the position of coroner of a New Orleans parish. He owned, and for many years personally conducted, the City Hospital for Contagious Diseases.

Correspondence.

REPORT OF CASES OF ENCEPHALITIS LETHARGICA REQUESTED.

To the Editor of the Medical Record:

Sir:—Reports have been received from various European cities which indicate the prevalence in epidemic form of a disease which has been named encephalitis lethargica. The first case of the disease in this city was reported to this department on March 12, 1919, and information has since been received from authoritative sources that there are eight other cases under observation in which this disease is suspected. In view of the fact that it is essential for us to be apprised as promptly as possible of the occurrence of cases of this disease, so that we may take such measures as may in the premises be necessary, I would earnestly request the cooperation of the physicians of this city in making prompt report to the Director of the Bureau of Preventable Diseases of any case in which encephalitis lethargica is definitely diagnosed or suspected.

The situation at the present moment does not seem to warrant our making this disease reportable by a Sanitary Code enactment, and I look forward with confidence to the cordial and helpful cooperation of your readers in giving us prompt information as to cases of this disease.

Royal S. Copeland,
Commissioner.

Department of Health, City of New York.

COMPULSORY HEALTH INSURANCE.

To the Editor of the Medical Record:

Sir:—The following resolutions were passed at a meeting just held by Rensselaer County Medical Society. The various county medical societies that are still to pass upon the subject of health insurance, as suggested by the president of the State Medical Society, might well take them as a model for their findings. They can hardly be improved upon, either in spirit or in form.

Resolved, That each and every practising physician, surgeon, nurse and dentist in the County of Rensselaer pledge themselves to oppose the passage of the bill; that each one of them visit in person or write the Governor, Senator and Assemblyman of their respective districts protesting against the bill; that they pledge themselves under no circumstances to enter into any contract under this health insurance law.

Every physician in the State might well follow this example if he wants to preserve his right to practise medicine as an independent calling, and to protect 80 per cent. of the population from a form of contract medicine forced upon them without their knowledge or consent by labor politicians anxious to pose as benefactors of their class and as dispensers of medical charity by the State.

New York. John P. Davin, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, February 20, 1919.

The Ministry of Health Bill.—Dr. Christopher Addison, the new president of the Local Government Board, presented to the House of Commons this week a bill "to establish a Ministry of Health and a Board of Health to exercise in England and Wales and in Scotland respectively powers with regard to health and local government and for purposes connected therewith." The bill, which was read for the first time, followed almost exactly the lines which I was able to surmise in a previous letter (see Medical Record, Nov. 9, 1918), in that it provided primarily for an assortment, under one government department, of duties which are at the present moment discharged by six or seven departments, with consequent waste of time, overlapping of energy, and aggravated expense. The third clause of the bill provides for the transference to the Ministry of Health of (*a*) all the powers and duties of the Local Government Board, (*b*) all the powers and duties of the Insurance Commissioners and the Welsh Insurance Commissioners, (*c*) all the powers of the Board of Education with respect to attending to the health of expectant mothers and nursing mothers and of children who have not attained the age of five years and are not in attendance at schools recognized by the Board of Education; (*d*) all the powers of the Privy Council and of the Lord President of the Council under the Midwives Acts, 1912 and 1918; (*e*) such powers of supervising the administration of Part I of the Children Act, 1898 (which relates to infant life protection), as have heretofore been exercised by the Secretary of State.

This is an immense pooling of intercurrent and concurrent activities, and must lead in the immediate future to consolidation and improvement in much that counts for sociological progress as well as scientific reform. The reasons for wide and anomalous distribution of medical duties have disappeared, and as none of the existing government departments wished to be confirmed in their medical work it is certain that no objections will be raised on the part of the old bureaus so long as the new bill gives promise of an equally adequate or more promising discharge of the necessary functions.

The following clause has distinct scientific significance: "The power conferred on the Insurance Commissioners by the proviso to subsection 2 of section sixteen of the National Insurance Act, 1911, of retaining and applying for the purposes of research such sums as are therein mentioned shall not be transferred to the Minister of Health, but the duties heretofore performed by the Medical Research Committee shall, after the date of the commencement of this act, be carried on by or under the direction of a Committee of the Privy Council appointed by His Majesty for that purpose, and any property held for the purposes of the former committee shall after that date be transferred to and vested in such persons as the body by whom such duties as aforesaid are carried or may appoint, and be held by them for the purposes of that body."

The Medical Research Committee, a powerful and discriminating body, with Sir Walter Fletcher as secretary, has hitherto been an appendage of National Insurance, paid out of money raised for National Insurance, and presumably working for national health through the Insurance Commissioners. This delimitation of its scope, always an unfortunate one, has been removed, and under the Privy Council the Medical Research Committee will have greater opportunities for wider work.

Clause 4 of the bill brings medical science into close cooperation with the Ministry of Health: "It shall be lawful for His Majesty by Order in Council to establish Consultation Councils for giving, in accordance with the provisions of the order, advice and assistance in connection with such matters affecting or incidental to the health of the people as may be referred to in such order. Every such Council shall include persons of both sexes, and shall consist of persons having practical experience of the matters referred to the Council."

This means that in every step taken the new ministry will have the prompt advice of the members of the medical profession, of those most fitted to give it, if (and if only) the personnel of the Consultative Councils are well selected. The difficulties which lie in the way of the government are largely met if the provision in the bill for medical Consultative Councils results in the assistance in public health legislation of medical men who are truly representative of professional interests.

Sir George Newman, at the present moment principal medical officer to the Board of Education, has been offered and has accepted the post of principal medical officer to the Local Government Board, and on him will devolve, as a secretary of the board, the administrative duties of the new department. The appointment is a practical step toward that coordination of public medical service which was avowedly the primary object of the Ministry of Health. With one medical man as minister, and another as chief of the executive staff, the new bureau should have no difficulty in adjusting the interests of medicine and those of the public rightly.

Death of Miss Eva Luckes.—The Matron of the London Hospital has died this week, to the great sorrow not only of the institution with which she had been so long connected but of the whole nursing world. Miss Luckes' death occurs at a position in nursing in which not only all hospital administration but the public also is deeply interested. Miss Luckes was appointed matron of the London Hospital 37 years ago, at the then extraordinarily young age of 26. The London Hospital, in the early eighties, though already the largest or the second largest charitable institution of the kind in the metropolis, was as far behindhand in all decent amenities for its nurses as any smaller or more struggling institution. The nurses were hardly worked, badly paid, coarsely fed, and insufficiently accommodated; their strenuous activities and grave responsibilities were discharged in a terribly trying environment. Miss Luckes at once proved herself a reformer, and during her thirty-seven years of tenure the women under her charge were steadily treated on a juster and humaner plan, until both in daily environment and future prospect they had every reason to be satisfied. But *pari passu* with the improvements in the nursing conditions at the London Hospital similar improvements were made at all the great charitable institutions, while the vast developments in medical and surgical nursing made the avocation of a hospital nurse a more dignified and scientific affair. Nurses, under such conditions, had to be technically educated to a high pitch, and from a body of women so equipped a movement sprang that they should receive the protection of State Registration. While the nurse at the great general hospitals was not considered to be fully equipped for her delicate and arduous duties until she had undergone a severe training as domestic servant, probationer, nurse, and head nurse, at hundreds of other institutions any young woman with no special education whatever acquired the right to the title of "Nurse," and, having done some sort of training, or no sort of training, at her institution, could then go to the public and demand large fees per week as a "trained hospital nurse." The movement for the registration of nurses had for its object the standardization of the nurses' calling. It was a demand that the woman who had undergone training of a certain duration and character, and this training in a hospital having a certain number of beds giving the necessary range of experience, should receive from the State a place on a registration roll, and should thereby be entitled to treat with the public for private professional service as a registered hospital nurse. It was also demanded that no woman who had not been thus registered should use the title of "Hospital Nurse" or sell her services to the public as such. The movement was, however, not unanimous among nurses, and Miss Luckes, the pioneer in the improvement of her order, stopped short of desiring State registration, no doubt largely because her own personal efforts at her own institution had convinced her that thoroughly capable nurses who would be most valuable to the public in all conditions of disease could be turned out on the more flexible pattern imposed by the authorities of the London Hospital. Of several points at variance between the two parties one alone need be mentioned. It is the principal one: How long should the training be of the competent nurse? Miss Luckes considered two years at a good hospital was sufficient. Those who were defining the process of registration desired three years' training at least. At the present moment the nursing world is still unsettled in its mind as to exactly what methods of training and what form of registration are required in the interests alike of the public and themselves. But the probability is that the more progressive party will win. One bill for the Registration of Nurses has already received the necessary parliamentary support, and this, or an analogous measure, may at any time be revived. A recognized curriculum of nursing training extending over at least three years, and protected by qualifying examinations and the registration of such qualifications, are things that are sure to happen in the near future. Miss Luckes was justified in her own attitude by her own personal success, but she too modestly considered that all sorts of large institutions could lay their hands on a leader of broad sympathies and strong capacity similar to her own, so that a homogeneous pattern of nursing would evolve from a large number of widely differing centers. She did splendid work, and this work will be carried on rather in spite of than because of her latest attitude toward nursing questions. Such matrons as Miss Luckes cannot be obtained by advertisement, but only by training. The whole nursing world, however, is extending deep sympathy with the London Hospital in the loss sustained by her death. She received official recognition during her lifetime which made her practically the head of the nursing world. She was appointed Lady of Grace to the Order of St. John of Jerusalem, she received the First Class of the Royal Red

Cross, and quite recently the C. B. E. Her "Textbook of Nursing" and her "Lectures to Sisters" are well known and appreciated.

Program of the National Council for Combating Venereal Diseases.—The following are some of the more important resolutions which have been passed at a recent meeting of the Council, presided over by Sir Thomas Barlow, late president of the Royal College of Physicians, London, who is particularly well qualified to guide the Council. For Sir Thomas Barlow was the president of the last International Congress of Medicine, held in London the year before the war, and on the international evidence received at that congress the British National Council for Combating Venereal Diseases arose: That the Local Government Board should authorize the appointment of whole-time venereal officers (a man and a woman) on the staffs of the medical officer of each county or county borough. (The women could usually combine venereal and infant welfare work.) That the present hospital accommodation should be supplemented by "ad hoc" clinics under the supervision of such venereal officers in every town of over 10,000 inhabitants, and also in the county boroughs, such clinics to be open for continuous and early treatment both for men and for women, and visited at frequent intervals by the venereal officers, who should be empowered to call in practitioners resident in each locality to assist them. It is suggested that a subsidiary appointment of clinical assistant could be given to a resident practitioner in each center, who would supervise the continuous and early treatment in the intervals between the visits of the venereal officer. That the Local Government Board should be asked to consider immediately whether some modified form of confidential notification of infective cases could be adopted under existing powers, and whether at a later date fresh powers could be obtained from Parliament. That hospitals and medical schools be requested to arrange special post-graduate courses for the training of medical women in the modern methods of treatment; a strong appeal is made to medical women to specialize in this subject. That some means should be devised whereby medical practitioners are encouraged to diagnose venereal disease in patients and also to give early preventive treatment. In the meantime the Local Government Board could secure the services from the Military Medical Department of three or four of the recognized authorities on venereal disease, and arrange for them to hold conferences with the local medical men in various parts of the country, with a view to devising the best means of securing efficiency and continuity of treatment.

A fourth resolution postulated that men serving in the Navy and Army, if in an infective condition from venereal diseases, should be retained in the service until their cure is complete, and not allowed to return to civil life in a dangerous plight to themselves and the community; while a fifth postulated a statutory obligation upon all men and women, whether within or without Government service, to continue treatment for venereal diseases *until cured*. (In the case of gonorrhea in the female this is a very large demand.)

Other resolutions dealt with the protection of young women and mental defectives, and the last one ran as follows: That the Home Office be asked to encourage each town and county to appoint an adequate number of women police without delay. The comprehensive nature of the program is obvious, and the desire to obtain female assistance and to develop the service of female patrol is commendable.

Progress of Medical Science.

5. Postinfluenza Alopecia.—Oscar L. Levin draws attention to the frequency with which alopecia occurs as a sequela of influenza. It appears from three to eight weeks after the influenzal attack, and is characterized clinically by the sudden thinning and falling of the scalp hair and occasionally by areas of incomplete baldness. The prognosis is usually good. Treatment includes the improvement of the general nutrition and local stimulation. The ultraviolet rays from the mercury vapor lamp are of value in the local treatment.

10. Vestibular Reactions in Five Hundred and Forty-One Aviators.—Louis Levy calls attention to the fact that an excellent physical equipment is demanded of the flying man, and therefore the rigid examination that is given includes the usually accepted methods of examining for vestibular apparatus. In view of the discussion that has arisen concerning these tests and the doubts that have been cast upon their value, Levy gives the results of observations made during a year's work in the Air Service Division of the Surgeon-General's office. Statements have been made that repeated stimulation, such as experimental whirling or flying, lessens the reactions. The author points out that if this were so it would be an important point in considering aviation since aviators are subject to constant stimulation of the vestibular apparatus during flight. With this in view a series of examinations were made of fliers from Barron, Carruthers and Taliaferro fields, the

examinees varying from cadets to officers who had flown 1,000 hours. It was found that nystagmus is not diminished by repeated turnings. Although vertigo was not timed, past-pointing and falling were slightly diminished in fliers of 100 hours' or more experience, being most noticeable in fliers who have had the greatest number of hours. As past-pointing and falling are objective signs of vertigo, this diminution was due to the fact that the flier had learned to interpret this vertigo and for the same reason more rapidly recovered his poise.

13. The Migratory Appendix.—J. E. Allaben refers to the fact that there are certain types of tumors in the abdomen, usually cystic in character, that become attached by adhesions at a point distant from their origin and finally become detached entirely from their original locality, their nutrition being maintained through blood vessels in the new adhesions. The fact that these are known as migratory tumors suggested the caption of the present article. He points out that it is not difficult to understand that the appendix might be subjected to a similar condition, and he reports a case in illustration of this. The patient, a woman aged 23, had been treated for a gonorrheal infection for nine months. She recovered sufficiently to discontinue treatment, but a year later reappeared, complaining of pain in the right iliac region. The pain became so acute that she was confined to bed. There was nausea, elevation of temperature, increase of pulse rate, and tenderness in the right iliac region on pressure. An exploratory examination revealed a considerable mass of omentum adherent in the right iliac region, the intestines being kinked and firmly adherent to each other, and covered with a yellow plastic exudate. The right fallopian tube was distorted and adherent, and upon its removal the distal end of the appendix was observed protruding about half an inch through a mass of adhesion in the right iliac fossa. The appendix was dissected out as thoroughly as possible, and 4 ounces of ether poured into the pelvis and right iliac fossa. Patient made a good recovery without complications. Commenting on this case, the author says that it is difficult to tell whether the appendix or the tube was primarily the offending organ. It is interesting to speculate as to what pathological condition would have followed if such an appendix had been left entirely to nature. In his own opinion, the appendix and the adhesions would ultimately have been absorbed without causing any trouble, but a tube with a patulous extremity periodically leaking pus into the peritoneum might have caused serious complications. He adds that this condition of the appendix may account for some of the cases reported in which no appendix was found.

1. Hunterian Lecture on the Surgery of the Spinal Cord in Peace and War.—A. J. Walton states that in choosing the subject of his lecture he has been guided by the fact that our knowledge of the symptoms of spinal injury has been enormously increased during the war, and the indications for operation more clearly defined. On the other hand, the prognosis after operation, and especially after the purely exploratory operation so often advised, when really contraindicated, has been so poor that its value in civilian lesions is tending to be unjustly depreciated. The pathological changes in the cord are extremely variable, and in the case of extra and intradural tumors consist at first of simple compression, followed by inflammatory changes. Our knowledge of such cases is slight, as those which do not recover and progress to a fatal termination have already passed on to a later stage when the opportunity for studying them occurs. In more advanced cases the consistence of the cord alters; the affected part becomes grey in color and on microscopic section will show a general increase of interstitial tissue, degeneration of the nerve elements, and abundant masses of myelin. In extreme cases all the fibers may be destroyed but there is never actual division of the cord itself. Although described as inflammatory in nature, these changes are in reality reparative and only a means of replacing by scar the destroyed tissue; they therefore do not tend to spread. The onset of these destructive changes is not due to the site of the lesion, but to the rapidity of its progress. In malignant disease of the vertebra the inflammatory change is always more marked than the compression, whereas with slowly growing tumors and in tuberculosis of the spine compression is the more marked factor. It is well recognized clinically that the more rapid the onset of paraplegic symptoms the worse the prognosis. The same law holds good if the pathological process is situated in the substance of the cord itself. Elsberg has evolved a technique for the removal of intramedullary tumors and has recorded several recoveries. In one of the lecturer's cases, which he believes to be unique, a centrally situated tubercular abscess gave rise to a partial paraplegia; the abscess was opened and complete cure followed. If, then, the general principle be true that the amount of destruction of the cord, and therefore the prognosis, is dependent neither upon the site nor upon the nature of the lesion, but upon the rapidity of its progress, marked changes would be expected from a traumatic lesion where the whole course of the disease is almost instantaneous, and the present war has shown this to be the case. Holmes has found that where the cord has been directly injured a portion may be disintegrated, so that on excision of the pia a semifluid, custard-like material may escape. Around this there are marked edema and multiple minute hemorrhages chiefly into the grey matter. The edema may extend to several segments, and bears no definite relation to the severity of the wound. There are also distant lesions and irregular patches of focal necrosis. Holmes also found that in cases where no direct injury of the cord had taken place and the dura was unopened, changes occurred which could only be attributed to concussion or commotion. In such cases microscopically there were punctiform hemorrhages with edematous swelling and diffuse or focal necrosis, and even complete destruction of all the functional elements of the cord. Collier believes that injury in these cases is due to a sudden rise of pressure and states that the changes are more marked in the lower part of the cord, as it is more closed below. He describes two other pathological changes that may occur, namely, organization of clot around the roots of the cauda equina and total necrosis of the distal portion of the cord, which Walton considers to be extremely rare. In cases of gunshot concussion where there was no visible injury of the cord or meninges, Claude and Lhermitte have found local patches of necrosis which they describe as insular necrosis. Such patches are usually situated at the level of the injury, the nerve elements being in process of destruction or completely transformed, while the neuroglial elements are proliferating and new blood vessels are being formed. In some cases the interstitial elements die and the focus is absolutely necrotic. In addition there are diffuse changes, which they have called "acute primary degeneration of the spinal tracts." Here the axis-cylinders are seen broken up in larger or smaller fragments and the nerve fibers for the most part have lost their parallelism. Around the broken fibers are grouped the granular bodies of neuroglial origin. In the grey matter the ganglion cells are loaded with lipochromes and the protoplasm appears full of chromophile granules fused in large irregular clumps. Clinical symptoms in spinal tumors are relatively slow in onset and tend to be focal in nature. The difficulty is therefore rather that of diagnosing the nature and site of the lesion than of determining whether or no a portion of the cord is destroyed. If pressure can be removed the cord will probably recover. In cases where disease commences in the vertebræ specific symptoms gener-

ally antedate those of interference with the function of the cord or its roots. In tuberculosis, for instance, pain, rigidity, and deformity will usually have been in existence long before the onset of paraplegia. In the later stages this localized pain will be replaced by the characteristic root pain. However, every case showing an onset with such localized pain should be examined for the presence of a primary focus, which is most commonly in the breast. The presence of root pains, which are the first of the actual cord symptoms to appear, has been taken to mean that the tumor is extramedullary; but this is by no means always so, the symptom being not uncommon with intramedullary tumors. Hunt and Woolsey have found that in intramedullary lesions such pains are likely to be unilateral; in one of Walton's cases, however, an extramedullary tumor was associated with unilateral root pain. It will probbaly be found that in the latter case the motor loss is confined to one leg, while the central tumor is more prone to cause bilateral paralysis. In the same way the presence of root pain is not a true indication that the tumor is situated posteriorly or laterally. The position of the pain may lead to errors in diagnosis of the level of the lesion. Although the level of the initial root pain is of the first importance in determining the site of the lesion, later symptoms may suggest a much higher level owing to stasis of the cerebrospinal fluid. A careful history must therefore be taken of early symptoms. Hunt and Woolsey have described cases of extramedullary tumors in the cervical region with distinct girdle sensation or constriction at the umbilical level which disappeared after removal of the growth and Reynolds has shown that the explanation of this may be that the pain is due to pressure on the sensory fibers in the cord, in which case it is referred to an area considerably below what one would expect from the situation of the cord lesion. It must be remembered also that in cases of chronic spinal meningitis there may be a band of hyperesthesia extending over a relatively wide area. Motor symptoms depend to a certain extent upon the site of the lesion. In extradural disease the pressure is usually more diffuse and the symptoms are frequently bilateral; when the lesion is situated within the dura, on the other hand, symptoms are generally unilateral. As a rule paralysis below the lesion is of a spastic type. Later the limbs may become flaccid with loss of tone. It is on such cases that the older views of association of a complete lesion with flaccidity and loss of tone were based. Recent experiences of war surgery show that it is possible, however, that this condition of flaccidity may pass off and be followed by a condition of extensor spasm, if the disease be not associated with sepsis of the urinary tract. At the level of the lesion itself there will be a segmental paralysis of the lower neuron type with wasting and complete flaccidity; this symptom is of great value in locating the level of the lesion in the cord, and may, indeed, be of more value than the level of the sensory changes, which are rarely found below the level of the lesion. The amount of sensory loss varies with the site and rate of growth of tumor; extradural lesions usually give rise to more diffuse pressure on the cord and hence all types of sensation are likely to be affected. In tubercular lesions there is loss of sensation only in the later stages, but in cases of secondary carcinoma the reverse is true. Before the war the condition of the reflexes in lesions of the cord was regarded as settled. It is in regard to the reflex changes with complete lesions that our views have undergone the greatest change. Walton points out, therefore, that neoplastic formations interfering with the functions of the cord give rise to focal symptoms which may remain localized for a prolonged period. The destruction of cord will vary with the rate of growth, and in slowly growing tumors may be relatively slight, while in the more rapidly growing ones, although of relatively small size, much permanent damage may be done. Owing to the comparatively slow progress of the disease treatment will probably be sought long before there are symptoms of a complete transverse lesion. In determining the site of tumor, it is essential that each group of symptoms be considered. The apparent limitation of the lesion to one or more tracts is not a certain indication of the site of the neoplasm, although it is well to remember that intramedullary lesions tend to spread up and down the cord, whereas in the case of an extramedullary tumor more and more tracts are involved. With a traumatic lesion of the cord the problem is very different. Owing to the acuteness of the lesion there is at first complete loss of function of the portion of the cord below the injury, giving rise to a flaccid paralysis. Even in case of only partial destruction of the cord by the passage of a missile, the lesions are widespread and recovery unlikely. If the paraplegia remains complete, therefore, prognosis is poor. *X*-ray examination is of value as an aid in determining whether the cord has been in part or wholly divided. Since the whole question of operative interference depends upon the diagnosis of an incomplete lesion it becomes a matter of considerable practical importance to determine upon what symptoms such a diagnosis can be made. In the early stages it would appear that there are no distinctive symptoms. In either case there may be, within a day or two of the wound, a complete flaccid paralysis to the level of the lesion, sensory loss to a similar level, absence of all reflexes, and retention of urine. In those cases where there is return of some form of sensation and of motor power it is evident that the lesion is incomplete. It is in the less well defined cases where there is alteration in the reflexes alone that the greatest errors have arisen, operation having been performed in the belief that the lesion was incomplete whereas there was a complete division of the cord. On the other hand, the change in the nature of the reflexes is often the first indication of partial injury and that an operation should be undertaken. It is the failure to recognize these points of distinction that has brought discredit upon this branch of surgery. The changes in the reflexes have been fully described by Riddoch, who shows that in cases of acute trauma there are three stages: the period of flaccidity, when no distinction can be made between a complete and an incomplete division; the stage of reflex action, during which the differential diagnosis can be made; the stage when septic complications are present, onset of which may be delayed for a long period. Before undertaking operation the surgeon must have clearly in mind what benefit is likely to accrue to the patient from such intervention; it is useless to remove an aseptic bullet when the cord has been completely divided, or a tumor when the functions are irrevocably destroyed. In neoplasms and other lesions, even when the symptoms of paraplegia are complete, provided they are of short duration and there are no septic complications, removal of pressure is likely to be followed by complete cure. The rule is therefore to operate as early as possible, before permanent damage has been done to the cord. When the lesion commences in the bone, however, laminectomy is contraindicated; this is the case also when the symptoms are due to acute myelitis or a softening of infectious origin, or in cases of disseminated sclerosis. In traumatic cases, whatever damage there is, is done at the time of the injury and removal of depressed bone or metal will do nothing to restore the portion of cord destroyed. Operation should therefore not be undertaken until there is evidence that the lesion is incomplete, but when such evidence is present interference should not be delayed. It is of considerable importance, therefore, that the points of distinction between a complete and incomplete lesion, as enumerated by Riddoch, should be clearly understood. Symptoms which develop at a later date are due either to the collection of inflammatory exudates, to the contraction of scar tissue, or to the excessive formation of callus. In each case they are directly due to pressure, for the relief of which an operation should be performed without delay. In certain cases an operation performed for the relief of severe root pains may be justifiable. Operation should never be undertaken for the purpose of repairing an injured cord, either by suture or grafting; in such cases recovery could not be expected and intervention constitutes a risk to the life of the patient, is a source of disappointment to him and his friends, and is likely to bring the operation of laminectomy into considerable disrepute. As regards the technique of the operation the first essential is a wide exposure of the lesion. If the dura is thickened and shows no pulsation it should be opened. With an extradural lesion and an apparently normal dura and

cord, if there is no septic extradural focus, it is better to examine the cord, for the lesions of the war have shown that even with an uninjured dura there may be gross change in the underlying cord. Little can be done of a curative nature in such cases, but there is no increased risk and help may be obtained in reaching an accurate diagnosis. If there is a definite septic focus outside and no visible lesion of the cord or dura, it is better not to open the latter. In operating for the relief of root pains care should be taken that a sufficient number of roots are divided. Reports of a number of cases are given to illustrate the various points brought out in this lecture.

3. **A Treatment for Trench Fever.**—Major J. E. Sweet and Lieutenant H. B. Wilmer have obtained very encouraging results with collargol in the treatment of trench fever. They state that though fully aware of the history of the drug and of the fact that it, with other colloidal preparations, had failed to do all that it was claimed of it, it seemed to them that a trial was worth while for the following reasons: the drug differs considerably from other colloid silvers and there is no great evidence of particular worry about trench fever in the enemy literature. In the medical supplement of the "Daily Review of the Foreign Press," issued by the General Staff, War Office, and dated February 1, 1918, the following statement was made: "According to Richter, intravenous injection of collargol (10 c.c. of 1 per cent. solution) is a specific remedy comparable to quinine in malaria. Three injections at two or three-day intervals cure acute cases." The authors have tried this remedy in thirty-five cases, with uniformly good results. They point out that, of course, the number is too small to substantiate Richter's claim for specificity, and that such a claim cannot be decided until after general trial, but they hope that the treatment will be tried by other workers. In all the cases treated the collargol was immediately followed by marked improvement and recovery, the only point open to question being whether in some of these cases spontaneous recovery occurred. The authors state that as yet they have learned of no method of distinguishing between a case that will recover spontaneously and one that will spend the next six months in hospital. They point out that a pronounced reaction follows the intravenous injection of 10 c.c. of 1 per cent. solution of collargol, made in sterile distilled water, and that the patients often compare this reaction to their initial attack. They do not consider this reaction harmful, however. If the injection does not enter into the vein but passes into the cellular tissue, a decided inflammatory reaction may follow and may even lead to abscess formation. In the present series of cases injections were not always carried out at two or three-day intervals; but when this was done the reaction seemed to be less marked when the second injection followed the first after a short interval. Charts are given of seven of the cases treated.

The Bridge-Head. Sir Andrew Macphail, Kt.

1. **The Pathogenesis of Deficiency Disease.**—Lieutenant-Colonel Robert McGarrison, as a result of clinical, morbid, anatomical, histological, and bacteriological observations upon the pathogenesis of deficiency disease, has come to the following conclusions: (1) The absence of certain accessory food factors from the dietary—improperly termed "anti-neuritic"—leads not only to functional and degenerative changes in the central nervous system, but to similar changes in every organ and tissue of the body. The morbid state to which their absence gives rise is not a neuritis. (2) The symptom complex resulting from the absence of these substances is due (a) to chronic inanition; (b) to derangement of function of the organs of digestion and assimilation; (c) to disordered endocrine function; (d) to malnutrition of the nervous system, and (e) to hyperadrenalinemia. (3) Certain organs undergo hypertrophy; others atrophy. Those which hypertrophy are the adrenals. Those which atrophy, and in the order of severity named, are the thymus, the testicles, the spleen, the ovary, the pancreas, the heart, the liver, the kidneys, the stomach, the thyroid, and the brain. The pituitary gland showed in adult birds a slight tendency to enlargement in males only. (4) The enlargement of the adrenals is a true hypertrophy in so far as it is associated with a proportionate increase of the glands' adrenalin content. The quantity and quality of adrenalin in the hypertrophied organ is, area for area, approximately the same as that found in the adrenals in health. The hypertrophy is equally well marked in both sexes. (5) Edema has invariably (100 per cent.) been associated with great hypertrophy of the adrenal glands, while 85 per cent. of all cases having great hypertrophy of these organs had edema in some form. The amount of adrenalin, as determined by physiological methods, in such cases has been considerably in excess of that found in cases not presenting this symptom, and greatly in excess of that found in normal adrenals. (6) Inanition gives rise to a similar state of adrenal hypertrophy, and to a similar state of atrophy of other organs, the brain excepted. (7) The edema of inanition and of beriberi is believed to be initiated by the increased intracapillary pressure which results from the increased production of adrenalin, acting in association with malnutrition of the tissues. Failure of the circulation and venous stasis may subsequently contribute to it. Age is an important factor determining its occurrence. This finding is held to account in great measure for the occurrence of "war edema" among prisoners of war in Germany. (8) Wet beriberi and dry beriberi are essentially the same disease; the former differs from the latter in the greater derangement of the adrenal glands. (9) Gastric, intestinal, biliary, and pancreatic insufficiency are important consequences of a dietary too rich in starch and too poor in "vitamines" and other essential constituents of the food. It is suggested that some of the obscure metabolic disorders of childhood might be examined from this viewpoint as well as from that of endocrine gland starvation. (10) A state of acidosis results from the absence of socalled "antineuritic vitamines"; this state is due to the imperfect metabolism of carbohydrates and to acid fermentation of starches in the intestinal tract. Clinically it is evidenced by progressive slowing and deepening of the respirations. (11) Great atrophy of muscular tissue results from deficiency of accessory food factors; it is due in part to the disturbance of carbohydrate metabolism in consequence of disordered endocrine function, in part to the action of the adrenals in supplying blood to the vegetative organs of the body at the expense of the muscles. (12) Profound atrophy of the reproductive organs is an important consequence of "vitaminic" deficiency. It leads to the cessation of the function of spermatogenesis. In the human subject such degrees of atrophy would result in sterility in males and in amenorrhea and sterility in females. This finding is held to account in great measure for the occurrence of "war amenorrhea." (13) The central nervous system atrophies little; paralytic symptoms, when they occur, are due mainly to impaired functional activity of nerve cells; much more rarely to their degeneration. (14) It is thought that because of their atrophy out of all proportion to other tissues, the thymus, the testicles, the ovary, and the spleen provide a reserve of accessory food factors for use on occasions of metabolic stress. This reserve, however, is rapidly exhausted. (15) The bones are thinned, and there is a loss of bone marrow. (16) The red cells of the blood are diminished by about 20 per cent. (17) The whole morbid process is believed to be the result of nuclear starvation of all tissue cells. Even the adrenals, which alone of all organs of the body undergo enlargement, show on section changes in some of their cells indicative of nuclear starvation. Accessory food factors are nuclear nourishers. (18) Finally, although deficiency of certain accessory food factors is the essential

etiological agent in the genesis of beriberi it is held that infectious and parasitic agencies are often important causes determining the onset of symptoms. "Vitaminic" deficiency renders the body very liable to be overrun by the rank growth of bacteria. The full details of the research which led to these conclusions will appear in the *Indian Journal of Medical Research.*

1. The Abdominal Tumors.—Fred W. Lux deals in this paper with abdominal tumors from the diagnostic aspect only. With regard to ascites he points out that it is not usually difficult to diagnose when the amount of fluid is equal to three pints or more; smaller quantities produce no definite physical signs. If the quantity of fluid is large the abdomen presents a rounded, globular appearance, the umbilical region being most prominent. If the quantity of fluid is large, but its accumulation gradual, bulging of the flanks is the most prominent feature. By placing the hand on the abdomen in the right or left hypochondriac regions, and depressing it suddenly, the fluid is displaced and the surface of the liver or spleen, provided they have been enlarged, can be felt. This phenomenon of "dipping" is considered pathognomonic of ascites. Less than three points is often difficult or impossible of determination as the fluid spreads itself in the abdomen and pelvis and occupies the interstices between the viscera without producing any sign of its presence. Unusually large and mobile cysts of the ovary, mesentery, omentum, peritoneum, and liver sometimes simulate ascites. The distinguishing characteristic of ascitic fluid is the readiness with which it changes its position in obedience to the laws of gravity and the change in the patient's posture. As for phantom tumors, they all disappear under an anesthetic. Most do so when the patient is asleep. In cases where a tumor disappears suddenly a displaced organ is probable. In enlargement of the kidney, which may be due to a tumor in the kidney, palpation, which is of far more importance than inspection, is best performed when the intestines have been emptied thoroughly. The area of dullness runs from the lateral aspect of the plain to the median line posteriorly. The tumor usually retains the shape of the kidney, and in the process of its enlargement it projects forward and downward. It may be felt easily, as a rule, bimanually. Exploratory puncture of renal tumor in the lumbar region has often been recommended, and in certain affections, such as hydronephrosis, echinococcus cyst or cystic kidney, it is certainly of advantage upon the condition that an operation is carried out immediately. In discriminating between the various enlargements of the liver we have to consider the form and shape that the liver takes, and whether the edge is altered. The consistence of the liver is of great diagnostic importance, whether it is hard, very hard, or only just about the normal consistence. The character of the surface has also to be taken into account. The general enlargements of the liver are usually of a uniform character, such as nutmeg liver, enlargement due to obstruction, and distension of the bile ducts. Cirrhosis of the liver is less often uniform, especially the hob-nailed atrophic form, but syphilitic cirrhosis and unilobular varieties may be quite uniform. Cancer of the liver gives the hardest liver and a cirrhotic liver offers great difficulty of diagnosis from cancer of the liver. Appendicitis is the most frequent abdominal emergency, manifesting sometimes a tumor, which the physician is called upon to diagnose. In the typical cases the diagnosis may be said to be never in doubt. In a case of tumor in pyloric obstruction, one has to distinguish between malignant and benignant growth. History of the case is often of great aid in diagnosis. Of all the causes of pure menorrhagia, fibromyoma of the uterus stands out by itself as the only important growth associated with the symptom, and a bimanual examination, as a rule, suffices to show that such a tumor exists, the chief characteristic of such a growth being an asymmetrical enlargement of the uterus, the typical shape of the organ being altered. The only physical method of examination which is of any assistance in determining an enlargement of the gall bladder is palpation. As in the diagnosis of gall bladder enlargement, so with diagnosis of spleen enlargement palpation is the best means of detection. A tumor of the head of the pancreas generally causes jaundice by invading the orifice of the common bile duct. A pancreatic tumor is situated back of the stomach, and to distinguish it from a tumor of the liver we have to dilate the stomach. One very important diagnostic sign of a pancreatic tumor is that no definite edge and no notch can be felt.

4. The Value of the "No-Good"-Minor Surgery and Influenza.—Douglas H. Stewart says that if one were to piece together and to formulate all the various opinions and guesses at opinions about the disease termed "the Flu," the final statement would be something like this: The general practitioner and his treatment must be belittled and made of no account, for many general practitioners are making good in the prevailing epidemic, and eventually a sound plan of procedure will become established. Therefore the public must be taught that the services of the general practitioner are valueless and the practitioner himself must be impressed with the utter hopelessness of the situation, lest he look out. It is well known that where there is no hope, there is no endeavor. Whether this be but a superficial reading of the times or a correct reading, is a matter of small moment, for the figures we have of gloom and protest from college or laboratory will turn into spray when they meet the rock of experience as exemplified by the man who is versed in the art of minor surgery and who is working in some mining camp or in the small but well equipped hospital of some industry. A letter from such a man states: "You told me to shut the patient's mouth, to open his sphincters and to lock up all my coal tars. Our men have a big value, for they are producers and want to get these points into print, for they have been worth more to our sick workers than the combined 'torkee, torkee' of the eight medical journals that come to me." Stewart goes on to draw attention to the fact that one of the first things that a minor surgeon does is to make up his mind that whatever the influenza is, it is not lobar pneumonia, or any other disease name; it is a thing he knows well, only he calls it sepsis or toxemia. It is a poisoning, and the pathology is as varied as is that of any other poison. The surgeon knows toxemia, and it follows as a matter of course that the surgeon considers breathing through an open mouth as much on the same plan as a sanitarian regards a well in a cemetery. The patient's mouth is foully contaminated and the inspired air is passing through a cesspool. When accompanied by pyrexia the local effect of mouth breathing is an inspissation or drying of the natural secretion of pharyngeal and other mucous membranes, and this imitates, to a certain extent, the artificial production of a coughing and vomiting by means of a finger when purposely inserted. Stewart holds that if in a septic case the mouth is left open all treatment is useless, for the outlook is grave and is fast becoming hopeless. Any person may become expert at freeing a stuffy nostril through practise upon himself, employing for the purpose a cotton-wrapped and vaseline-coated probe. It is pointed out that when we are dealing with a toxemia that spends much of its force upon the brain or its membranes, against the respiratory organs, and within the alimentary canal, when we have shut the mouth and freed the nostril, we have, by the very act, put the cerebral circulation, together with the intake of the respiratory and of the digestive systems, into a closer approach to the normal. Stewart emphasizes the vital importance of opening the sphincters in order to avoid gastric dilatation or paralytic ileus, or both combined, which is the consequence of closed sphincters where toxemia is present. He suggests that the treatment of influenza should begin with the identical therapeutic post-operative precautions taken by a surgeon—the hourly 1-10 grain of calomel, the alum enema and the rectal tube. A sum-

mary of the situation might be expressed as follows: "Is the mouth shut, is the nostril free, and is the rectum right?" If not, it should be made so, otherwise we cannot hope to have any structure right, if it lie between the mouth and the rectum, because the whole machinery of head, thorax, and abdomen is more or less crippled; it is only the degree of crippling that may be called in question. No structure in the whole body is immune to a severe poisoning that is taking place in any part of the alimentary canal. Why should one be asked to imagine a doctor who wasted his time looking for a pulmonary consolidation to explain a toxemia that was so evidently coming from a digestive tract, both ends of which tract were damaged machinery and its lumen contents were fairly rotted, because of a palsied contraction and its accompanying, though undiscovered stasis—a stasis that prolonged massage might easily have removed, or which might have been arrested by such simple means as packing the rectum with a vaseline-soaked gauze strip?

Prosthesis of Limbs.—G. Körting publishes his experience and offers some critical remarks tending to react against the present tendency to excessive improvements in prosthesis of limbs. After an experience of four years the writer found that many amputated subjects preferred a rigid wooden leg to one with a complicated mechanism. Subjects with amputated arms usually experienced deception following exaggerated promises and complicated operations when first coming under treatment. The majority of them hang up their artificial arms in a closet after having uselessly battled with them for some time. A rigid arm with a hook at the end renders far more service than Sauerbruch's arm. Prosthesis, however, is useful in intellectuals and still more so in those who have lost both arms and cannot educate a remaining intact member. The one great defect in all forms of prosthesis resides, Körting holds, in the absence of sensibility which prevents the subject from getting more than a certain degree of usefulness from the apparatus employed.

Myotomy of the Forearm in Cases of Digital Contracture.—A. Salomon has treated a contracture in flexion of the fingers following a cicatrix on the forearm by total division of the muscles followed by separation of the divided parts. The writer then grafts a flap of fat over the muscles to take the place of the aponeurosis, and insists upon the necessity of filling the parts where muscular regeneration is to take place from all external pressure. In the case reported by the writer muscle regeneration was quite well advanced at the end of three months, the force of flexion was almost normal in the fingers, and the circumference of both forearms was equal. When the muscles of the arm were made to contract the regenerated portion became quite as rigid as the rest, a fact which, Salmon says, proves that the regeneration was muscular and not fibrous.

On Wound Diphtheria.—Anschütz and Kisskalt recall that the diagnosis of the diphtheritic nature of a wound cannot be made simply from its aspect. Just as there may be an absence of membranes, so existing membranes may be due to bacteria other than Loeffler's bacillus. The writers observed this wound complication develop progressively, the first cases having escaped diagnosis. When at last the attention was drawn to the possibility of a diphtheritic wound infection, examination showed that 15 per cent. of hospital patients, as well as 19 per cent. of out-patients, were carriers of the diphtheria bacillus in their wounds. The virulence of the bacilli was verified by guinea pig injections. The throat and nose of subjects carrying bacilli were examined and only gave positive results in 33 per cent. of the cases. The writers endeavor to explain the innocuity of the bacilli in certain wounds by a state of immunity acquired from a former diphtheria. The treatment by serotherapy appears to have exercised a happy influence on this type of diphtheria intoxication, especially in the more serious cases. It is to be remarked that the writers' cases correspond with other epidemics of diphtheria wound infection occurring in other parts of Germany.

Wound of the Inferior Vena Cava from Exploding Shell, with Embolic Migration of the Missile.—Henes describes a case of tear of the vena cava followed by death, in which a small fragment of shell entered the superior vena cava, thence passed into the right auricle and ventricle and finally became lodged in one of the branches of the right pulmonary artery.

Censorship and Science.—H. Much reports an affair which admirably illustrates the danger of excessive bureaucratization of sanitary matters. Being sent to stamp out an epidemic of cerebrospinal meningitis, Much commenced by making thorough examinations of the rhinopharynx in subjects suspected of actually having being exposed to the disease. Perceiving that the number of carriers of the meningococcus attained fantastic proportions as the epidemic progressively decreased the writer composed a report showing that these carriers were not dangerous to others. The censor did not allow the report to be printed, on the pretext that the writer's conclusions were contrary to established facts. A second report, with data to back up the statements contained, was absolutely ignored by the censor.

The Absorption of Nitrogen and Atmospheric Air in Artificial Pneumothorax.—K. Henius has undertaken experiments on dogs to ascertain if nitrogen or air offered any differences in their manner of absorption when injected directly into the pleural cavity. It results from the tables published by the writer that the differences sometimes in favor of nitrogen, at others of atmospheric air are insignificant, so that air can be perfectly well used in place of nitrogen for practical reasons. And still more, the intrapleural pressure does not offer a rigorous proportionality with the amounts injected, a fact to be interpreted by the variation of certain factors, such as the tonus of the diaphragm or respiratory muscles, the elasticity of the mediastinum, etc. Neither is there any relationship between the tension of the injected gas and the rapidity of absorption.

Poliomyelitis in the Army.—A. Stern reports five cases of acute poliomyelitis occurring in the German army, although there was no epidemic among the children in the region where these cases occurred. However, the writer remarks that the coexistence of influenza should be given attention, all the more so because the coexistence of these epidemic diseases has already been noted. One of the patients had had the grippe six weeks before he developed the poliomyelitis. Stern also learned that two other of his patients came from a region where there had been a high mortality among hens.

Fatal Mercurial Poisoning Following Sublimate Injections for the Cure of Varicose Veins.—F. Hammer resorts to Linser's treatment for the cure of varicose veins which consists in injecting the ectasic vessels with a 1 per cent. solution of $HgCl^2$, a treatment quite extensively employed in Germany and recommended in the army by the medical board. In the fatal case met with by the writer the dose injected was only one centigram of the salt. A typical mercurial intoxication resulted with stomatitis, colitis, and nephritis. The writer recalls the accidents observed during various mercurial treatments, and concludes that in these patients there is an idiosyncrasy for the drug and that, therefore, there is no reason for renouncing the treatment of varices by this procedure. In the case reported it must be supposed that the intoxication was due to a failure of coagulation, such as ordinarily takes place at the time the injection is given, and for this reason there was a rapid diffusion of the mercury throughout the system.

SECTION ON SURGERY.

Stated Meeting, Held January 3, 1919.

DR. SETH MILLIKEN IN THE CHAIR.

Large Chondroma of the Ribs Associated with Exostoses of Humerus and Tibia.—Dr. JOHN C. A. GERSTER presented this patient, a man 60 years of age, who came to him on April 26, 1918. There was a history of trauma nine months previously. The patient was carrying a package in both hands, slipped, and was unable to put out his left hand to save himself; he fell, striking his left lower thorax against a radiator. There was a bruise and later a swelling which "came and went," but was not troublesome. At the end of three months there was a definite lump, and at the end of six months this lump began to grow much more rapidly. He did not consult a physician until nine months after the injury. At that time there was a tumor the size of the palm of the hand, projecting like a plateau one inch from the chest wall; its center was elastic. An *x*-ray showed that the tumor projected much further internally than externally, its shadow almost touching that of the transverse processes of the vertebræ intra-abdominally. The lower margin of the tumor corresponded to the free border of the ribs, and its upper margin came just below the eighth rib. At operation May 30, 1918, a large skin flap was made with base uppermost, the incision beginning at the median line half way between umbilicus and ensiform, skirting the lower margin of the tumor and curving slightly upward in the back, ending about two inches and a half from the median line behind. The skin and subcutaneous fat were peeled from the deep fascial surface covering the tumor from below upward to well beyond its upper margin. The abdomen was opened by an incision corresponding to the lower margin of the tumor. Manual exploration determined the absence of adhesions. Successively, one inch of the 12th, 11th, 10th and 9th ribs were resected; the soft parts were then divided, opening the thorax in a vertical direction. Under guidance of the fingers within the thorax the soft spots of the 8th intercostal space were divided along the upper margin of the tumor, which was now freed below, behind, and above from the abdominal and thoracic parietes. The costal cartilages were divided in front; the only attachment now was that of the diaphragm, which was cut away from the inner aspect of the mass. The left lung, pericardium, and diaphragm showed no gross pathologic changes. Closure was begun by suturing the free edge of the diaphragm to the cut edge of the abdominal muscular wall. There was considerable pull of sutured diaphragm upon the pericardium; to relieve this an incision was made through the upper surface of the diaphragm (down to, but not involving, the fascia or the peritoneum on its abdominal surface) in a direction parallel to the pericardial margin and one inch away from it. The skin and subcutaneous tissue flap was turned down to where its inner surface touched the diaphragm without tension, and the left pleural cavity was then closed by a running catgut suture uniting subcutaneous superficial fascia to diaphragm about two inches below its cut edge. A running suture of silk closed the skin. The specimen weighed 1200 grams. The abdominal surface of the tumor presented coral-like excrescences and had a bony shell. The external surface was soft, covered by fascia, and incision here revealed an interior filled with clear, straw-colored mucoid fluid and cartilaginous masses. Microscopically, sections taken from this region showed pure chondroma (but there was no question that the tumor had osseous tissue in other parts, as demonstrated by the *x*-ray and gross pathological examination). The patient made an uneventful recovery. He was a little short of breath for a few months, and an *x*-ray taken a few weeks after operation showed the left lung to be less well aerated than the right. This slight dyspnea gradually passed away. The patient is well seven and a half months after operation, and has been able to resume his work as a foreman in a factory. An *x*-ray taken a few days ago failed to show any signs of recurrence. There was moderate scoliosis, with concavity toward the operated side. The patient also presented two bony exostoses—one of the humerus close to its neck, of forty years' standing; and one of the head of the fibula, of forty-two years' standing. While these would not absolutely place the patient in the class of thoracic chondroma with multiple exostoses, his case might well be considered in this relationship. The operation was performed under intrapharyngeal anesthesia administered by Dr. W. Brauower. A catheter of 18 French caliber was introduced through one nostril into the oral pharynx. The lung could be expanded or deflated at will during the operation. There was no dyspnea. Anesthesia was entirely satisfactory at all times. Because of its simplicity and equal effectiveness, intrapharyngeal anesthesia seemed preferable in operations where one or both pleural cavities were opened. On the other hand, intratracheal anesthesia was still the method of choice in operations upon the jaws and tongue, because it prevented entrance of fluid or mucus into the respiratory tract. There were a number of cases (mostly in the French literature) of large chondromata of the ribs removed without differential pressure where no dyspnea was noticed upon establishment of total pneumothorax by opening the chest. Besides these, there were several of sarcomata of the chest wall operated without differential pressure in which a considerable effusion had compressed the lung. Why there was no mediastinal fluttering in any of these cases we did not know.

Carcinoma of the Recto-Sigmoid; Colostomy for Acute Intestinal Obstruction; Balfour Sleeve Resection; Closure of Colostomy.—Dr. GERSTER presented also this patient, a man of 56 years, who gave a history of being perfectly well up to four days before admission to Mount Sinai Hospital (on Dr. Elsberg's service), when he began to suffer with abdominal cramps, vomiting and obstipation. Upon admission he presented the classical syndrome of obstipation, persistent vomiting, and marked abdominal distension. Through a median hypogastric exploratory incision, the cause of the obstruction was found to be an annular, freely movable carcinoma of the rectosigmoid, one inch above the floor of the pouch of Douglas. A left iliac colostomy was established (and opened twelve hours later). The original laparotomy wound was closed. Five weeks later this was reopened and, after a liberation of numerous adhesions, the tumor of the rectosigmoid was resected and the gut joined end to end by the sleeve method of Balfour. The patient left the hospital for about eight weeks after recovery from this operation. He then returned and an enterotribe was employed to cut through the spur of his colostomy. This was accomplished in five days. Two weeks later the colostomy was closed, and the man made an uneventful recovery.

Dr. L. T. LE WALD said that from the *x*-ray it would seem that there was some calcification on the inner surface of the chondroma in the first case presented, and he was interested in knowing whether examination had shown what caused that shadow.

Dr. GERSTER replied that he had forgotten to state that the original *x*-ray report of the patient before operation had indicated the tumor to be an osteochondroma. A few days before the present meeting, Dr. J. C. Bloodgood had seen the tumor and had remarked that it was curious to observe the bony shell on the intraabdominal surface and the absence of such calcification on the sub-fascial (external) aspect. There was no question but that there was some bone present in the growth.

Phlegmonous Gastritis.—Dr. GERSTER presented this specimen. The patient was a man sixty-five years of age, admitted to the service of Dr. A. V. Moschcowitz at Mt. Sinai Hospital, May 15, 1917, with a history of two days' abdominal cramps, vomiting, and constipation, but no previous history suggestive of gastric trouble. He presented the picture of a marked diffuse peritonitis, and because of greater tenderness in the epigastric region, a diagnosis of diffuse peritonitis following perforation of a gastric ulcer was made. An exploratory epigastric incision revealed a diffuse peritonitis; no perforation of the stomach, but the pyloric portion was markedly injected and thickened, in con-

trast to the apparently normal duodenum and fundus of the stomach. Flakes of greenish fiorin were present along the lesser curvature. Through the transparent lesser omentum, the pancreas could be seen and felt, apparently normal. The appendix and gall bladder were exposed and found normal. There was no fat necrosis. All lymph nodes in the abdomen were enlarged and palpable. The condition was diagnosed as a phlegmonous gastritis involving the pyloric portion of the stomach (ending abruptly at the pylorus) and causing the diffuse peritonitis. A drain was placed at the bottom of the pouch of Douglas through a suprapubic stab wound, the original incision being closed. A culture of the peritoneal exudate showed pneumococci. The patient died eight hours later. The specimen showed an enormous induration of the pyloric two-thirds of the stomach. This swelling shaded off gradually toward the cardia, but ended abruptly at the pyloric ring. On section the wall measured two centimeters in thickness in the diseased region, due almost entirely to a thickening of the mucosa and submucosa. In the submucosa were streaks of yellowish purulent exudate which could not be squeezed out. In the mucosa of the antrum were two large necrotic patches about three to four centimeters square and greenish black in color. Microscopical examination of the stomach showed throughout the entire greatly thickened wall a diffuse acute inflammatory process with much edema.

The Rôle of Cell Necrosis and Bacteria Invasion in Surgery.—Dr. FENTON B. TURCK read this paper. (See page 471.)

Dr. EDWARD LELAND KELLOGG said they had listened to a paper of surpassing interest and expressed himself as impressed with the profound learning, the daring thought, and the ingenious deductions of the author. He was surprised to find his name on the program and regretted that he had not had a longer period of time to draw conclusions from the clinical application of Dr. Turck's hypothesis. He had, however, read his earlier papers on this subject and been privileged to study a large number of his microscopic specimens. He had tried to follow his deductions, and, while admittedly lacking the special training fully to appreciate his line of thought, it seemed to him that Dr. Turck's carefully controlled experiments were entitled to earnest consideration. Dr. Turck had given new light on the cause of post-operative temperature which we had learned to expect, and it was comforting to know that when it occurred our patients were receiving an autoinoculation against infection. Clinically we had learned that patients with lacerated wounds might be in a measure protected against tetanus by the inoculation of a proper antitoxin. It was reasonable to believe that similar precautions might protect them against the more ordinary infections. That the absorption of the autolyzed tissue cells might give rise to serious symptoms was easy to believe, but that a serum could be prepared to protect the body against this effect was revolutionary and gave us food for thought because of its far-reaching possibilities. If clinical results bore out the laboratory findings it would seem that we had found the Aladdin's Lamp. To draw conclusions from clinical experience one must have a vastly larger number of cases that the speaker had treated; he was, however, glad to submit the following data. He had used the serum in nine cases, giving in all twenty doses, the maximum dose that he had given being 5 c.c. There had been no bad results. Apparently the serum was safe to use in this dose at least. Unusually there was a slight febrile reaction. One patient developed a scarlatiniform rash which disappeared in forty-eight hours. Dr. Kellogg gave somewhat in detail the cases in which the serum was used. One of the cases was a suppurative synovitis of the knee which had been treated by the Carrel-Dakin solution and in which they had expected trouble. This patient was cured. Two cases of osteomyelitis of the femur and one of extensive laceration of the thigh were improved by the serum treatment. One case of extensive burns had improved under the treatment, two others had died. In two cases of intestinal obstruction it was administered before operation. In both cases convalescence was uneventful. While this was a pitifully inadequate list from which to draw conclusions, it was his impression that the wounds had healed more rapidly and infection had been more easily controlled than would have been the case without the serum. The freedom from injurious effects and the results of Dr. Turck's carefully worked out and controlled experiments made him feel justified in continuing the clinical experimentation, upon which he hoped at some later date to report his experience.

Dr. JOHN LARKIN said he did not know why he had been called upon to discuss this problem, as it was a physiological and not a pathological problem. He hoped Dr. Meltzer would discuss it from the physiological standpoint. He wondered how many had read the report of Dr. Bayliss' work on the physiology of shock, which was conducted by the "Shock Commission" appointed by the Crown, of which Conner, Haldane, and Trowbridge were members. The consensus of opinion that they had given seemed to show that they had had very meager opportunities of observing shock cases, or what constituted the condition we knew as shock. This commission was appointed for the purpose of determining what shock was, what agents had a curative effect, and what might be deduced from their experiments that would be of value in saving the lives of soldiers. The experiments were conducted in conjunction with French physiologists and were all conducted on a physiological basis, and that was why he as a pathologist did not feel exactly competent to discuss the subject. The work that the physiologists had done in the Oxford and London universities had been amply controlled; he did not see that Dr. Turck had controlled his work in this way. He had given them glittering statements but no physiology whatever. The work of Bayliss and the Shock Commission, published in the *British Medical Journal* in May, 1918, showed that they had made very careful observations and gave specific proofs and suggested life-saving measures. They had listed many diagrams of blood pressures, temperatures, etc. Drummond and his associates had been most active in the field, and there was no doubt that all this work which was presented had been done before and offered nothing really new. It was done in 1914, and before that time in connection with work on blood pressure. Bayliss, Taylor, and Drummond saw exactly the identical conditions when they hammered dog's muscle to the injuries of muscle by shell wounds occurring on the battlefield. They had also proved that a deranged nervous condition had nothing to do with its production. They sectioned the spinal cord at the lower lumbar vertebra, hence eliminating any nerve factor. Another question arose in regard to shock, and that was, where there were no open injuries there might be fat embolism. Bayliss simply passed this over, but did not consider it a very important part of the problem. The condition of acidosis was another question. It seemed to him that there was no doubt that autolysis of the muscle really took place, and there was acid produced as the result of muscle digestion—acid which the French and English called lactic acid and we called sarcolactic acid. After all, Haldane had shown that the acid was not produced in such proportions as might cause death or very great changes in the system. Therefore, to control the acidosis factor, Bayliss used injections of bicarbonate in his experiments and says that the bicarbonate was not a counterpart of the lactic acid and that the lactic acid was but one of the factors that possibly involved acidosis. Dr. Larkin said that he had had the pleasure of looking over Dr. Turck's specimens, and up to the present time he was not absolutely convinced as to how he arrived at his deductions. He was perfectly free and frank in saying to Dr. Turck that he had not paid much attention to the changes pointed out by Dr. Turck; he formerly thought and still was of the opinion that the conditions were not brought about by the absorption of autolyzed muscle, but represented only agonal thrombi, so frequently seen in all microscopic preparations. There were three kinds of changes in the blood vessels and no injury to the intima, but mostly coagulation of the red and white cells and sometimes purely a coagulation of the serum, and that was the general picture. In regard to the changes pointed out he thought it wise to hold our judgment in abeyance for a more strict pathological confirmation. Another question, and that was immunization by injecting this serum into individuals supposed to be in shock or to prevent shock on persons about to undergo surgical operation. He did not think that immunity was brought about in just that way. The Shock Commission, in looking for some agency that would diminish shock,

had experimented with gum arabic, and brought out that it was one of the most effective agencies for combating shock given in a solution of 6 per cent gum arabic in 9/10 solution of saline, and injected intravenously. With this they had had most remarkable results in shock or in cases in which they were about to do an amputation. In the *Fourth British Quarterly* there were all the findings of the Shock Commission, and gum arabic saline was one of the things that stood out most prominently. We did not know that all the facts had been accurately sustained, but more careful work had yet to be accomplished. Dr. Larkin said he took this opportunity to compliment Dr. Turck on the great effort he had made in trying to clear up a difficult problem.

Dr. S. J. MELTZER said that instead of talking physiology, as Dr. Larkin had suggested, he would rather discuss what could be termed pathology. If he understood correctly, Dr. Turck thought very little of the value of germs in pathology; he compared them with the demons of old. He assumed that the main factor in the causation of disease was the destruction of tissue and the absorption into the blood of some polypeptids. Dr. Meltzer recalled an article by Dr. Cheesman and himself, which appeared about twenty years years ago in the third volume of the *Journal of Experimental Medicine*, describing experimental work carried out at the pathological department of the College of Physicians and Surgeons. They had introduced intravenously into normal animals colon bacilli, typhoid bacilli, streptococci, and staphylococci in large quantities without producing any untoward effect upon the animals and without being able to recover the organisms from the blood. If, however, previously to the injection an injury to some tissues was produced, for instance, by touching up with a hot glass rod some part of the liver, spleen, parietal peritoneum, uterus, etc., these injured places contained the organisms in pure cultures and the injection mostly led to septicemia. They arrived at a conclusion which was just the opposite of the view held by Dr. Turck. Dr. Meltzer assumed then and assumed today that pathogenic organisms (and their toxins) were the main cause of the development of acute diseases. But the organisms required for their growth and development a focus of dead tissue or at least of tissues with diminished vitality; bacteria did not gain a foothold in perfectly normal tissue. He did not deny that some protein material might exert a toxic effect, just as probably Dr. Turck did not deny that microorganisms might in some cases be the cause of a disease. At least he did remember that many years ago Dr. Turck claimed that he could produce gastric ulcer by feeding animals with large quantities of cultures of a colon bacillus. Dr. Meltzer referred, furthermore, to recent experiments published by Dr. Wollstein and by Dr. Kline in conjunction. They produced typical pneumonias by the intrabronchial injections of 1:20,000 Dakin's solution, or chloramine-T, and by injections of egg yolk into the bronchi, but not of egg white. Dr. Meltzer said that they were never so fortunate as Dr. Turck to produce pneumonias by mere spraying of the throat. The pneumonias thus produced were anatomically indistinguishable from normal pneumonias produced by cultures of pneumococcus. The fundamental difference between the two kinds of pneumonias was that the chemical pneumonias did not lead to the death of the animal and the blood, as well as the tissues, remained sterile. Here again the essential danger from the pneumonias was the presence of bacteria. Dr. Meltzer looked upon the anatomical changes merely as a part of the processes of defense and repair, and not as essential part of the fatal disease, a view which Dr. Meltzer advocated for many years. Dr. Turck had said so much in his paper, and said it so quickly, that Dr. Meltzer could not say with how much of that which Dr. Turck said he agreed or disagreed. He only wished to say that the pictures presented by Dr. Turck did not support any view of this kind. As to shock, Dr. Meltzer said he was one who had to confess to being guilty of having worked with various collaborators on this subject. All who worked on shock on the battlefield, as well as in the laboratory, were of the opinion that it was quite difficult to produce a condition of shock. Recently he and his coworkers published a method by which they were able to produce shock in a little less than ninety minutes. He was therefore greatly surprised to hear that Dr. Turck could at will produce shock within a few minutes. It seemed to him that such a rapid effect was more liable to be accounted for by embolism than by shock. Much more interesting and important was the statement of Dr. Turck that he developed a serum which could prevent shock. Dr. Kellogg used this serum, he believed, in eight cases. But as far as he understood Dr. Kellogg, there was not a single case of shock among them. They were simply cases of injuries, among which two or three recovered sooner; that meant, say, in three instead of four weeks. Now all of us knew that this might happen often enough, not because of a certain treatment but even in spite of it. At any rate, the shortening of a recovery from four to three weeks had nothing to do with the statement that serum could prevent shock and that shock could be produced within a few minutes. As to the results of the physiological investigations of the various commisisons on shock, Dr. Meltzer did not feel that much was accomplished. Dr. Cannon, one of our leading physiologists, before leaving for the theater of war thought that in shock large quantities of blood in the circulation were trapped between the constricted mesentery and liver capillaries, and advised the use of intravenous injections of pituitrin. In Europe he met surgeons who made laparotomies on shocked patients and were quite sure that they did not find any engorgement of the vessels of the abdominal viscera. Cannon gave up his previous theory and became a follower of the theory that acidosis was the main cause, and now recommended the intravenous injection of bicarbonate of soda. Bayliss, who previously recommended the intravenous injection of a 6 per cent. solution of gum acacia, agreed now with Cannon that the fluid for intravenous injection should consist of a 4 per cent. solution of bicarbonate of soda and of a 6 per cent. solution of gum acacia. He could not enter into details because some of the communications were marked confidential, but the following was public property: Bayliss gave up the idea that acidosis was the primary cause of shock and was not using bicarbonate of soda any more. On the other hand, reports came in from the battlefield that intravenous injections of a 6 per cent. gum acacia solution led in many cases to very serious results and even to deaths. Another disappointment was the theory of Porter that shock was produced by pulmonary fat emboli. The subject of fat emboli in the lung was treated exhaustively in 1913 in a monograph by Dr. Warthin, which apparently was not known to Dr. Porter. The most disappointing side in Dr. Porter's activity was that he was apparently by far not as good a diagnostician as he was a physiologist. From his statements we learned that he diagnosed shock merely by the effect of low blood pressure. Now pulmonary fat embolism could be easily diagnosed. The patient was cyanotic, suffered from air hunger; pulmonary edema and sometimes hemoptysis were present; auscultation revealed rales, and the blood, urine, and even the sputum showed the presence of fat droplets. These were characteristic symptoms, but Porter did not indicate anywhere that he looked for them. Dr. Turck told us marvelous things and the speaker did not wish to deny them, but he regretted that Dr. Turck did not bring forward any evidence that his statements were reliable and correct. It would be well for the subject if other experimenters would be in a position to verify his statements. Lantern-slide demonstrations of anatomical pictures did not prove his physiological contentions.

Dr. ROBERT T. MORRIS asked if they had a man with spinal anesthesia and injury to the sciatic nerve, and they did a hip joint operation which was accompanied by no shock, what part the spinal cord, the sciatic nerve, and the spinal anesthesia played in that phenomena.

Captain DEIIELLY expressed the opinion that we were not as yet able to say what shock was. If it was necrotic tissue that produced shock we ought to have a great deal of shock, but among a large number of wounds there had been very few cases of shock. They had many cases of gas gangrene beginning after a short lapse of time and no shock at all accompanying them. They sometimes met with intoxication from a badly wounded limb, but if they removed the limb there would

be no more intoxication and there might be no shock. In the case of crushed limbs, if a lower limb was crushed there they would have shock and death, but if an upper limb was crushed there would be no shock. The speaker had tried many different forms of treatment for shock without obtaining any definite results. He had tried gum arabic, bicarbonate of soda, saline, and blood transfusion, and it was his experience that in true shock there was no remedy that was effective. In regard to the necrotic tissue there was one point he wished to bring out, and that was that one might have necrotic tissue without infection. If one had a special form of infection, as the Welch bacillus or streptococcus, one might have a very great deal of infection, but necrotic tissue alone seemed to give no trouble in wounds. Many times he had seen gangrene localized without any symptoms and without the disease being propagated through the blood-vessels, and if they would remove the infected muscle they would have no grave condition. Shock occurred many times from very slight wounds going just through the skin, while in large injuries to the muscles there might be no shock. The question was a very large one and very difficult to settle. He felt, like Dr. Meltzer, that we had no good theory and no means of diagnosing shock. There was one point, however, that was perfectly settled, and that was that necrotic tissue alone did not mean anything, but if bacteria were present they would cause trouble. With reference to the effect of bacteria getting inside of the stomach, he did not think we should say that we had autolysis first or infection first, for we did not know. Captain Dehelly said he had not done any physiological experimental work himself, but he had seen a great deal done by Dr. Carrel, and it was very difficult to arrive at any just idea of what shock was.

Dr. TURCK, in closing, said that the discussion had brought out splendid evidence corroborative and confirmatory of the statements made in the introduction of the paper, namely, that at the present time we knew nothing about the cause or etiology of shock. We had studied as physiological problems the secondary manifestations of shock, such as fall in temperature, fall in blood pressure, and acidosis, all of which varied exceedingly, *i.e* the fall in temperature did not always correspond to the fall in blood pressure, nor was the acidosis necessarily in proportion to the degree of shock. As to the alleged failure of some observers to produce experimental shock, the speaker said his clinical surgical experience had taught him to recognize shock; and in his experimental work, by the exposure of the viscera, by trauma, by taking the tissue from the lungs and introducing it into the larynx and lungs of homologous animals, by various chemical, physical, and mechanical means, and by the injection of chloroform, he had produced the identical condition in animals recognized clinically as shock. Now the statement was made that tissue autolysis did not produce shock for the reason that in certain instances in which there was tissue autolysis there was no shock. Cannon, in his recent report, had abandoned all the old theories and thought that shock was due not primarily to a loss of vasomotor tonus, nor to fat embolism, but that it was the result of tissue traumatism. Before the meeting of the Société de Biologie, which met on November 28, Pierre Duval and Delbet said this meeting would be historic because it was the first time that biologists, physiologists, internists, and surgeons had met together and agreed almost unanimously on the toxic origin of shock. Dr. Quenu had come to the same conclusion, stating that apparently the victims of shock were poisoned with toxins that might cause death either by rapid action on the nervous system or by acting on the liver or other organs. All these men were agreed that it was the absorption from the wound that produced these conditions which we called shock. In regard to the statement made by Dr. Larkin, whose wide experience and splendid work they all appreciated, that he had been seeing the changes which were shown this evening for twenty years, this was corroborative evidence of the point brought out in the paper that the changes shown were the primary changes both in shock and disease, which he was glad Dr. Larkin had seen, though he had not placed upon them the interpretation which the writer of the paper had endeavored to bring out. Again, when it came to treatment, all the theories of shock as based on fall in temperature, blood pressure, acidosis, etc., failed completely, and surgeons were compelled to fall back on the removal of tissues. This was empirical, but the speaker's experiments had served to explain the scientific basis. It had been shown that if a ligature was placed on the leg of an animal and the leg injured, the animal suffered no shock; but when the ligature was removed the animal went into shock and died within three hours, and that was the reason they were practising débridement. It had been shown, both by his own experimental work and that of others, that shock could be initiated without the presence of bacteria. If one introduced chloroform, tissue necrosis would follow without the introduction of any bacteria whatever. The points that he wished to emphasize were that shock could be produced by chloroform and by many other means, to which reference was made in the paper; that this shock was similar to that produced by wounds and disease, and that it was possible to immunize both animals and human beings against shock due to tissue autolysis. Wound injury in itself was not the cause of shock; the cause lay in cell autolysis and disintegration, and this placed the problem not alone in the domain of physiology but also in that of colloidal chemistry. This work on shock and wounds had developed a fundamental principle in the causation of many obscure acute and chronic diseases. Many of these were now amenable to treatment by immunization against the effect of cell necrosis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 24, 1919.

THE PRESIDENT, DR. CHARLES HOWARD PECK, IN THE CHAIR.

Executive Session.

Resolutions Empowering Cooperation with Other Societies.—Dr. E. ELIOT HARRIS introduced resolutions asking that the Committee on Public Health of the New York County Medical Society be empowered to join with committees from other county societies for purpose of acting in an advisory capacity on matters of hygiene and public health. This resolution was for the purpose of permitting the Public Health Committee to consult with similar committees from the Bronx and Kings County Medical Societies.

This resolution was unanimously adopted.

Resolutions on Prohibition Amendment.—Dr. E. ELIOT HARRIS, chairman of the Committee on Public Health, reported on the resolutions opposing the ratification of the prohibition amendment introduced by Dr. J. P. Davin and referred to that committee at the last meeting of the society. He stated that this resolution read:

"That the Medical Society of the County of New York opposes the ratification by the Legislature of New York of the measure now before it for national prohibition as irrational, unscientific and in opposition to the accepted usage of all civilized nations elsewhere throughout the world, and as putting upon the medical profession the burden of prescribing and dispensing alcoholic beverages of proved therapeutic worth, while allowing the unlimited sale to the public of patent, proprietary and quack remedies containing alcohol in varying amounts without control or hindrance by the officers of the State."

In connection with these resolutions Dr. Harris read the resolutions adopted by the House of Delegates of the American Medical Association, at its 1917 meeting in New York City, opposing the use of alcohol both as a beverage and as a therapeutic remedy, and said that the committee recommended that no action be taken on the resolutions. It was pointed out that if the society adopted these resolutions it would be adopting something that had no meaning whatever, inasmuch as the Legislature of the State of New York had already ratified the Prohibition Amendment to the Constitution.

A very lengthy, and at times turbulent, discussion followed, during which all varieties and shades of opinion on the prohibition question were expressed. An amendment was introduced which practically nullified

the import of the resolution. After a further discussion the amendment was voted down and the original resolutions adopted by a vote of 49 to 23.

In order that certain amendments to the Donohue bill, providing for compulsory health insurance, might be considered, a motion to postpone the scientific part of the program and to devote the remainder of the session to the discussion of these amendments was carried.

Report of the Committee on Compulsory Health Insurance.—Dr. Eden V. Delphey, chairman of the special committee appointed by the society to make an intensive study of the subject of compulsory health insurance, presented this report, which stated that the committee had conferred with both professional and lay persons interested in the subject and offered the following amendments to the Donohue bill, Assembly Bill No. 90, for the consideration of the society. In so doing the committee wished it distinctly understood that it in no wise committed itself in favor either of the Donohue bill or of the scheme of compulsory health insurance as a whole; that it simply presented the amendments to the bill so that if some such bill was enacted into a law the interests of the medical profession might be properly protected and safeguarded; and in order that there would be sufficient inducements for highly qualified men to enter the profession in the future with the result that the health and physical well-being of the people at large would be properly and adequtaely cared for. The following amendments were submitted, voted on and adopted seriatim:

Amend Article I, Section 2, page 3, line 13, by adding a sub-paragraph defining "panel." "Panel means a body of physicians duly licensed and registered according to law and corporated under and in accordance with this chapter."

Amend Article I, Section 3, page 3, line 25, by striking out the word "and" in the clause specifying certain exceptions; and Section 3, page 4, line 2, by adding the following: "and employees whose wages are more than one hundred and twenty-five dollars per month," so that it shall read: "excepting employees whose employment is not in the usual course of trade, business, profession or occupation of the employer, employees of the United States, employees of the State and municipalities, for whom provision in time of sickness is made through legally authorized means which in the opinion of the Industrial Commission are satisfactory, and employees whose wages are more than one hundred and twenty-five dollars per month."

This amendment was inserted because as the bill now stood there was no limit as to the salary of those receiving the supposed benefits of the bill, and a man receiving a salary of a number of thousands of dollars per year would be included under the provisions of the bill as well as the laborer whose wages were very moderate in amount.

Amend Article II, Section 12, page 5, line 26, by striking out the entire section and substituting therefor the following:

"12. Medical and Surgical Service. Local, trade and establishment funds make arrangements for medical and surgical attendance and treatment for insured persons and the dependent members of their families with the Panel provided for hereunder, and such arrangements shall permit insured persons to have free choice from among the members of such Panel, subject to acceptance by such physician of such insured person as a patient. No member of the Panel shall at any one time undertake or have charge of the care and treatment of more than five hundred insured persons with the dependent members of their families, and in computing such quota two insured persons without dependents shall be equivalent to one insured person with dependents. All arrangements for medical and surgical attendance and treatment shall include compensation to be paid therefor, and such compensation shall be determined in accordance with a schedule or schedules fixed by the commission in conjunction with the Panel."

Article II, Section 13, page 6, line 19, to be amended by striking out all such section and substituting the following:

"13. Hospital or Dispensary Treatment. Funds shall furnish instead of all benefits hereunder (other than cash benefits to dependent members of insured person's family and funeral benefits) hospital or sanatorium treatment and maintenance of insured persons upon the consent of the insured person or that of a member of his family when it is not practicable to obtain his consent. Funds shall furnish dispensary treatment when necessary. Hospital, sanatorium or dispensary treatment shall be furnished only when requested by the insured person upon the approval of the medical officer of the fund, or when recommended by the attending physician in such case. All medical and surgical treatment given insured persons hereunder in hospitals, sanatoriums or dispensaries shall be given by physicians, surgeons or specialists who are members of the Panel under arrangements provided for in accordance with Article II, Section 12, of this Chapter. Provision for such treatment and maintenance shall be limited to the period for which the sickness benefit would otherwise be payable, and shall be provided in a hospital, sanatorium or dispensary with which the fund has made satisfactory financial arrangements for maintenance, nursing and all other necessary care incidental to medical or surgical treatment, or in one erected and maintained by the fund."

Article II, Section 15, page 7, line 12, to be amended by striking the same out and substituting therefor the following:

"15. Medical Facilities. Funds shall provide for proper laboratory and other facilities for diagnosis and treatment, and in addition to arrangements for medical and surgical treatment shall make arrangements with dentists and with specialists who are members of the Panel for consultations, treatments and operations."

Amend Article II, Section 19, page 8, line 26, by striking out all of this section and substituting the following therefor:

"19. Maternity Benefit. Funds shall provide insured women and wives of insured men with such medical, surgical and obstetrical aid, materials and appliances as may be necessary for safe delivery in accordance with Article II, Section 12. When necessary for safe delivery, medical, surgical and obstetrical aid under this section shall be given in hospitals or sanatoriums upon the approval of the medical officer of the fund and the recommendation of the attending physician, surgeon or obstetrician. Such aid shall be provided in a hospital or sanatorium with which the fund has made satisfactory financial arrangements, or in one erected and maintained by the fund. Arrangements for medical, surgical or obstetrical aid in such hospital or sanatorium shall be made with the Panel in accordance with the provisions of Article II, Section 12, of this Chapter, Funds shall pay weekly to insured women a cash maternity benefit equal to the regular cash sickness benefit of the injured for a period of eight weeks, of which at least six shall be subsequent to delivery. Cash maternitiy benefit shall be paid upon a certificate of the medical officer of the fund that the beneficiary is abstaining from gainful employment during the period of payment. Benefits under this section shall be in addition to all other benefits under this Chapter."

Amend Article IV, Section 56, page 18, line 23, by striking out lines 23, 24, 25, 26 and by substituting the following therefor:

"Make arrangements with the Panel, hospitals, sanatoriums, dispensaries, in accordance with Article II, Section 12, and with laboratories, institutions, dentists, pharmacists and other persons necessary for the conduct of the business of the fund."

Amend Article V, Section 81, page 25, by striking out lines, 12, 13 and 14, and substituting therefor, the following:

"Arrange for the formation of such state and local advisory bodies to be consulted on medical and other technical matters relating to this Chapter as may prove necessary, and fix their powers and duties, including the power and duty of investigating the operation of the system of mutual health insurance established under this Chapter, and of recommending to the Industrial Commission measures for improving the system's administration."

Further amend Article V, Section 81, page 25, line 19, by inserting after the words "hospital treatment" the words "dispensary treatment."

Further amend Article V, Section 81, page 25, line 21, by inserting between "(3)" and the words "financial arrangements" the following:

"Make schedules in conjunction with the Panel from time to time, at least once a year, of the fees and compensation mentioned and provided for in Article II, Sections 12, 13, 15 and 19 of this Chapter, and in the making of such schedules the said Commission shall take testimony of any witnesses that it may desire to call and of such witnesses as the Panel may present. Such schedules when adopted or made by the commission shall be subject to a right of review, as provided for in Article V, Section 83, of this Chapter."

Amend Article V, Section 83, page 27, line 2, by inserting the word "appellate" before the word "jurisdiction."

Amend the bill by changing Article VI on page 27 to read Article VII, and insert new Article VI, and number Section 90 so as to make Section 93, as follows: "Article VI, Panel."

"90. Division of State into Districts. The Industrial Commission shall within 60 days after this Act shall take effect divide the State into districts and each such district shall contain approximately 500 physicians duly licensed and registered as such in such districts."

"91. Organization of Panel. The Industrial Commission shall thereupon cause to be published in one newspaper published in the county where such district or districts shall be located, a description of the territorial boundaries of such district, and shall designate each district by number and county. Each physician duly licensed and registered according to law within such district shall be deemed thereupon for the purpose of organization to be a member of said Panel, and shall be entitled as herein provided to participate in the organization of said Panel. Within 30 days after the publication of the boundaries of any district as hereinbefore provided the members of the Panel in said district shall meet and elect from their number a representative for the purpose of effecting the incorporation of the Panel under this Chapter. Each such representative shall receive upon his election from the chairman and secretary of the meeting a certificate sworn to by them that he is the representative chosen in pursuance with the provisions of this section. Upon the filing of said certificate with the Industrial Commission there shall be issued by the said Commission to such representative a certificate under the seal of said Commission as evidence of his election. Within 60 days after the publication of the said boundaries of said districts the said Commission shall set a time and place when the said representatives so elected shall meet for the purpose of organizing the said Panel. The said representatives shall therupon become the incorporators of the Panel provided for in this Chapter. The said representatives shall thereupon proceed to complete the organization of said corporation according to the provisions of the membership corporation law of this State. The said corporation, when organized, shall have all the powers of a corporation under the corporation law, and such powers in addition thereto as are necessary to effect the purpose of this Chapter. Membership in such Panel shall continue subject to rules promulgated by the Commission after being formulated by the Commission in conjunction with the Panel."

This amendment provides for one State-wide Panel.

The attention of the Society was called to the fact that the first fundamental proposition adopted by the society in December, 1916, providing for "adequate and proper representation on the Commission and on all other bodies having to do with medical matters" was not included in the amendments offered by the Committee, and the explanation was given that there was another Bill, Assembly Bill No. 93, which arranged for placing the administration of the Act under the Industrial Commission and the appointment of a fourth Deputy Commissioner to have charge of Compulsory Health Insurance. On motion the Committee was directed to formulate an amendment to Assembly Bill No. 93 embodying the principle referred to.

The proposed amendment is as follows:

Suggested Amendments to Assembly Bill No. 93, Introduction No. 93. Introduced January 13, 1919, by Assemblyman Charles D. Donohue.

Amend the Bill by inserting on page 1, line 1, between the words "section" and "41" the word "forty."

Amend the Bill by inserting on page 2, line 2, a new Section as follows:

"Section 40, Industrial Commission Created. There shall be a Department of Labor, the head of which shall be the Industrial Commission. The Commission shall consist of [five] *seven* Commissioners appointed by the Governor by and with the advice and consent of the Senate, one of whom shall be designated by the Governor as Chairman. *Two of the said Commissioners shall be duly licensed and registered practitioners of medicine of the State of New York.* Upon the appointment of a successor to the chairman, the Governor shall designate such successor or any member of the Commission as chairman thereof. The term of office of each Commissioner shall be six years [except that the term of the Commissioners first appointed shall expire one on January 1st, 1917, one on January 1st, 1918, one on January 1st, 1919, one on January 1st, 1920, and one on January 1st, 1921.] *The Commissioners in office at the time this Act becomes a law shall remain and continue in office for the balance of their respective terms, and the additional members provided for herein shall be appointed so that the terms of office of one of the said additional Commissioners shall expire on January 1st, 1922, and that of the other said additional Commissioner herein provided for shall expire on January 1st, 1923."* The balance of the Section to remain as in the present Section 40.

Matter in brackets [] to be omitted; in *italics*, new.

Dr. Daniel S. Dougherty, in the course of the discussion, made an eloquent appeal to the members of the Society to avoid commercialism in dealing with this problem, recalling the evangelist St. Luke as a great physician who would not accept as an honorarium the cash of the poor fellow who could not pay for his groceries or afford to send his children to school. He did his work for the good of humanity; to him the healing of the sick was more than a commercial proposition, and this was the ideal that had always guided the profession. Personally, Dr. Dougherty said he was in favor of State health insurance for the people and he would like to see the Graves bill passed. At the same time he wanted to stand by the doctors just as long as they upheld the traditional ideals in virtue of which they had always been willing to treat the indigent out of the goodness of their hearts and the greatness of their profession. In the study of the question of compulsory health insurance he hoped they would get away from the idea of commercialism and get away from themselves, and look at the problem from the viewpoint of its effect on the people.

Dr. J. P. Davin said he also wished to uphold the dignity of the profession and that they were not considering the question simply from the commercial viewpoint. The working people were not complaining of their doctor's bills. One might hear them complaining of the high price of the necessities of life, but when any one in their families was sick and in need of medical attention they received it at the hands of the doctor no matter what their financial status. He had many times taken the best men in the medical profession to the bedside of the poorest patients and the question of money was never brought up. Those men did their work for humanity and in doing it they won honor. Under compulsory health insurance the people would be robbed, the physician would be robbed, and the officers of the State would get the money. Instead of ratifying this bill by helping to make the machinery for its administration they should repudiate compulsory health insurance, root and branch, body and soul, and everything connected with it, as the county medical societies had done in Kings, the Bronx, Buffalo, and as they would do to-night in Syracuse. They should take the stand that they would not work under this compulsory health insurance law if it was put into effect.

Dr. William S. Gottheil said that compulsory health insurance, as pictured under this bill, was an idol with feet of clay. Those who were advocating it said that the beneficiaries under this scheme were to have the best physicians, the best surgeons, the best nurses, the best hospitals, the best druggists, and the best undertakers, but they had forgotten to say where they were going to get the money; they had no idea where the money was to come from, so the whole scheme was going to fall through of its own weight or degenerate into a lodge matter. Those amendments contained one point

of vital importance, and that was the paragraph on the incorporation of the panel. If there was going to be such a thing as compulsory health insurance, there was going to be a panel, and it must be incorporated, and this would be a power; it would be the first step toward a powerful medical profession in the State.

Dr. DAVIN opposed the idea of incorporation on the ground that "a corporation had no body to be hanged and no soul to be damned," and that it would soon bring the medical profession down to the level of politics.

After further discussion, all the amendments having been adopted separately, it was moved, seconded, and carried that they be adopted as a whole.

Dr. DELPHEY then introduced a resolution to the effect that as there were other bills having to do with the subject of compulsory health insurance before the Legislature, one of which provided for the administration of health insurance by the State Department of Health, that a memorandum embodying the fundamentals of the amendments just adopted be attached to all such measures and that adequate representation of the medical profession be provided for on all bodies having to do with the administration of health insurance.

This motion was adopted.

Miscellany.

Work of the Rubio Institute, Madrid, for the Year 1917-18.—This comparatively new medical institute, which consists of many separate dispensaries, with hospital accommodations, treats about 10,000 new patients annually and furnishes excellent clinical material for teaching. In the *Revista Ibero-Americana de Ciencias Medicas* for December is a summary for the year which ends during 1918. The number of classes is unusually large, and the chances for team work must be superior, but there is no mention of cooperative efforts in the report. The first clinic mentioned is the surgical, which was visited by 643 patients, upon whom 173 operations were performed. The relatively small number is explained by the great number of surgical specialties which divide the other operative material. The gynecological clinic cared for 268 patients, who submitted to 32 minor and 30 considerable interventions. There is a second clinic for gynecological and abdominal surgery, under Dr. Botin, which cared for 390 new cases, of which 70 required major operations. The *x*-rays and internal secretions are largely used in gynecological cases. The next clinic in the list is devoted to affections of the bones and joints—orthopedics in the widest sense; there were 410 patients who required 17 major and many minor interventions. There is also a second orthopedic clinic under Dr. Durén which registered 736 new and 857 old patients, with 65 major and 162 minor interventions. The first clinic for the ear, nose and throat registered 536 new patients, and the second 385. The two urological clinics cared respectively for 259 and 185 cases. The clinic for diseases of the anus and rectum registered 122, that for affections of the stomach 403 new cases. The pediatric clinics, three in number, one devoted to surgical cases, treated about 600 children. There were 35 minor and 36 major or medium operations performed in the amphitheater under full anesthesia. The ophthalmological clinic treated 428 patients, the clinic for diseases of the chest 723, the internist clinic 1139, the neurological clinic 485, the two clinics for skin and venereal diseases nearly 600 cases, the clinic for stomatology 358 and the radiotherapeutic clinic 73 patients.

Influenza in Mexico City.—As a rule since the pandemic of influenza has been in evidence we have been fed with sensational stories of mortalities backed up by estimates but not by facts. In the Public Health report for Mexico City for last November, just received here, the exact opposite prevails. There is no official notice of the existence of a pandemic of influenza, and to the best of our knowledge there have been no news items about enormous morbidities and mortalities in the medical or secular press. But the cold figures are that in the month in question in this one municipality of about 500,000 inhabitants the number of deaths from grippe amounted to 1402 without including 511 cases of bronchopneumonia, 641 cases of labor pneumonia, and 299 cases of acute bronchitis. These deaths add up to 2,853, while the total mortality for the month is 4,329. The total deaths for November, 1917, were 1,457 so that the pandemic has almost trebled the rate.

-RAY VISUALIZATION OF THE GUT BY MEANS OF A NEW INTESTINAL DELINEATOR.*

BY MAX EINHORN, M.D.,

NEW YORK.

OFESSOR OF MEDICINE AT THE N. Y. POST-GRADUATE MEDICAL SCHOOL, VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL.

1912 I devised[1] an intestinal delineator by means which the course of the duodenum and a part the small intestine could be mapped out by the

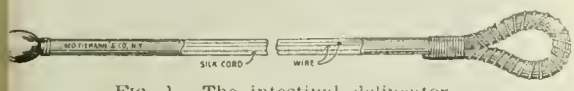

FIG. 1.—The intestinal delineator.

ray. The instrument consisted of a thin, very xible rubber tube (size 4F) through which ran o wires and a silk thread. At the end there is a metal ball. With a delineator about 3½ eters long I had been able to visualize by the ray the greater part of the entire small intesne. The actual length of small intestine thus monstrated by means of the instrument was over

G. 2.—*X*-Ray picture of patient H. A., with intestinal eator *in situ*. The course of the instrument in the stomduodenum, and part of the small intestine is distinctly ible.

9 eet.[2] Drawing out the instrument when it had reched the depth mentioned was done with difficulty, causing some discomfort to the patient. I became convinced that although the method was feasible it would not be practicable as a routine measure. It certainly appeared inadvisable to let the delineator pass further down into the small intestine, for the reason of the difficulty encountered in withdrawing the instrument.

Being desirous of studying the whole course of the small intestine, and possibly also of the large bowel, I constructed a new delineator, which can be given to the patient with the object of its passing through the entire digestive tract and leaving it in the natural way, by the rectum. In order to fulfill this purpose the delineator must be as flexible and pliable as a string and still possess qualities which make it visible under the *x*-rays.

FIG. 3. Patient with the new intestinal delineator in the digestive tract. (Schematic.)

The new delineator consists of braided silk through the lumen of which run 60 strands of annealed copper 0.002 inches in thickness. The string is about 30 feet long, and is attached to a small metal ball (about 20F). The string is provided with markings (made of lead surrounding the string and covered with adhesive plaster. The markings

1 2 3 4 5 6

are as follows: – – –

mits the delineator to be freely movable through it without encountering any friction, and which can be held in the mouth, between the teeth, whenever desirable. The free end of the string is then fastened to a reel and the delineator wound over it, so that the holder and the metal ball form the free end of the string on the reel.

I am indebted to Mr. A. D. Scott, engineer, and Mr. A. E. Pfarre of Tiemann & Co. for the successful construction of the instrument.

Method.—The delineator is best given after a light breakfast, in the morning. The ball is put deep into the pharynx and patient given water to drink. The instrument thus starts its journey to the stomach and then further down through the entire digestive tract. The reel is put in a pocket

Fig. 4.

Fig. 6.

Fig. 5.

Fig. 7.

not too far from the mouth, and attention is paid that there be no obstacle to the unwinding of the string from the reel. *X*-ray pictures are best taken every two hours during the day until the ball appears in the stool.

Fig. 8.

Fig. 9.

It is best to observe the following rules when employing the delineator:

1. When introducing the delineator, attach it in such a manner that it cannot go beyond 60 cm. This can best be done by fastening the string to the reel by means of a rubber band after enough length had been unwound so that 60 cm. can enter the mouth.

Fig. 10.

Fig. 11.

2. One-half to one hour later, detach it. The patient should not swallow it intentionally, and he should not keep his mouth closed too tight, but let the delineator go whenever there is a pull.

3. At night the holder should be pushed up to the teeth and held there in the same manner as when smoking a cigar. It is appropriate to fasten the holder to a tooth, whenever feasible, or to the

Fig. 12.

cheek. Care must be taken, however, not to interfere with the gliding of the delineator, which must be freely movable along its path.

4. The delineator should be unwound from the reel from time to time for about 30-50 cm., so that it hangs loosely in the form of a curve.

5. When washing or dressing, the patient must be careful not to disarrange the delineator.

6. While eating, the delineator must always be fastened to the reel by means of a rubber band, in such a manner that not more than 30-50 cm. can move into the stomach during the meal. The latter having been finished, the rubber is taken off and the delineator released.

7. Defecation must be performed over a commode. When the metal end piece appears in the feces the patient should carefully lift it out of the latter, clean it, wrap it in gauze, and attach it to the underclothes. The patient should inform the physician of the passage of the end-piece. The physician now cuts the delineator at the lips and allows this part of the string to enter the stomach. At each defecation the delineator must be disengaged from the stool, cleansed, wrapped in gauze, and attached to the underclothes until the whole delineator has passed. The latter should be handed to the physician.

8. An *x*-ray picture should be taken a few minutes after the delineator has entered the stomach; then every 2 or 3 hours, from 9 A. M. to 5 P. M., up to the time when the end piece appears in the stool, when the last plate is taken.

The new delineator was first used in October, 1918, on a patient of the Lenox Hill Hospital. The patient referred to, Mrs. A., took the new delineator on Oct. 14, and passed it per rectum on Oct. 18. During the whole course of the delineator's journey she experienced no discomfort whatever.

The series of plates* which I take the pleasure of showing you illustrate the different positions of the instrument along the digestive tract at different times. It will be best to go over them in their natural sequence.

Fig. 4-10. *X*-ray of Mrs. A., with the intestinal delineator in the digestive tract.

Fig. 4. Immediately after swallowing the instrument. The metal ball is visible in the stomach.

Fig. 5. Eighteen hours afterward. The cord of the delineator is seen partly curled up in the stomach, then running straight through all the intestinal coils; the ball is situated near the cecum.

Fig. 6. After 22 hours. The delineator represents a chart of the course of the entire small intestine; the cord runs through the gut in a single line, showing no curling up anywhere; then we notice the ball in the ascending colon, and above it the delineator curls up in spiral form upward along the course of the large bowel.

Fig. 7. After 24 hours. Same as Fig. 6. Curling of delineator in large bowel extends higher up and the ball has moved upward.

Fig. 8. After 46 hours. Same as 7. Ball is situated in the descending colon; the spiral formation is now seen principally here, surrounding the ball.

Fig. 9. After 50 hours. Ball visible in transverse colon (probably brought back there by antiperistalsis); almost the entire colon mapped out by spiral formation of the delineator.

Fig. 10. After 66 hours, and previous release of the delineator from its attachment. The cord is

Fig. 13.

filling out the colon in spiral formation and the ball is situated in the sigmoid flexure.

*I am indebted to Miss Leach of the Lenox Hill Hospital for the taking of the *x*-ray plates.

It can be easily seen from the above that the entire intestinal tract can be visualized by means of the delineator through the Roentgen rays. The following points seem to be of importance:

1. The delineator runs through the entire length of the small intestine without once curling up.

2. Different from the small intestine, in the large bowel there is seen a winding up of the string in screw form.

3. In the small intestine the ball always runs ahead of the string and drags the latter along. In the colon the string, in spiral form, is frequently found moving ahead of the ball.

These normal findings will probably be of diagnostic import in pathological conditions. In obstructions along the small intestine the ball will find an obstacle in its forward passage, and the string will then curl up.

The following plates* show the delineator in the digestive tract of a normal individual (R. F.), Figs. 11-13.

Fig. 11 is a radiograph of R. F. 3¼ hours after swallowing the delineator. The cord is visible along stomach, duodenum, and a portion of the jejunum. The young man, contrary to instructions, had swallowed the whole delineator (string) during his luncheon.

Fig. 12 shows the instrument lying almost like a hair-ball tumor in the stomach. Here it took longer for the string to disentangle itself and leave the stomach, but when it did it ran through the small intestine in the usual way without curling up. The markings on the delineator are well shown all along the digestive tract. It seems possible in this way to obtain an actual measurement of the length of the small intestine.

Fig. 13 shows the position of the delineator 56 hours after it was swallowed. The spiral formation is visible in the colon.

RADIOGRAPHIC TYPES OF INFLUENZAL PNEUMONIAS.

BY ELSIE FOX, M.D.

NEW YORK

ROENTGENOLOGIST, CITY HOSPITAL

THE four radiographic types herewith shown, which were found during the recent epidemic of influenza, may be of interest.

During the epidemic many patients were referred to the X-Ray Department of the City Hospital to confirm the clinical findings or to shed light upon the more obscure cases.

Out of eighteen cases selected at random, six died. Upon three of the six autopsies were performed. Two of the latter are illustrated below, Figs. 4 and 5.

Radiographically speaking, four general types were distinguishable, namely, lobar pneumonias, bronchopneumonias, the edemas, and those cases developing empyema. Before illustrating the pathological, it may be advisable to record a normal chest for comparative purposes.

FIG. 1.—Normal chest.

Fig. 1 is a roentgenogram of the chest of a healthy girl of twenty, who, as far as she knows, has never had any pulmonary involvement. The illustration shows both hemispheres equally well transilluminated, bases and apices clear, the root of the lungs formed by the bronchi, blood-vessels, glands, etc., casting a shadow normal in extent and density.

The other illustrations depict the four types as follows:

Fig. 2 illustrates a case of frank lobar pneumonia, showing consolidation of the right middle lobe, triangular in shape, the apex of the triangle pointing toward the hilus, and the base of the triangle extending toward the midaxillary line. When the roentgenogram was repeated a few days after

FIG. 2.—Lobar pneumonia.

the crisis no lightening of the dense shadow was discernible. The characteristic shadow of this type of pneumonia usually persists several weeks after the patient is discharged. As a rule, cases of this type recovered.

*I am indebted to Dr. Thomas Scholz, radiologist, for these beautifully executed *x*-ray pictures.

Fig. 3 illustrates the bronchopneumonia type, showing discrete, scattered areas of consolidation found throughout one or both lungs, having no predilection for any particular lobe. The case illustrated recovered.

Fig. 3.—Bronchopneumonia.

Fig. 4 illustrates the type of edemas with or without a small amount of hemorrhagic fluid in the pleural cavity. The majority of the cases belonged to this type. Exitus in the severe cases occurred in a few days. Both lungs show irregular and massive clouding due to the extreme congestion, particularly at the bases and apices. Patients having pronounced basal congestion usually died. This case at autopsy, performed two days after radiograph was made, revealed the following findings: Streptococcal and massive bronchopneumonia with multiple abscesses, gangrene, pulmonary edema and fibrino-purulent pleurisy with effusion; tracheitis and bronchitis.

Fig. 5 is a roentgenogram from a case of empyema. To this fourth group belong the cases that developed empyema. The radiographic findings

Fig. 4.—Edema with some pleural effusion.

were uniform. One or the other side of the chest was completely occupied by a dense shadow extending from the apex to the base. The fluid level could not be determined, since the patients were too sick to be radiographed in the upright position. At autopsy several liters of pus were found in the right chest of this case. There was atelectasis of the right lung. The left lung presented hypostatic congestion and an acute vascular emphysema.

Fig. 5.—Empyema.

In the four pathological cases illustrated, the clinical conclusions and radiographic findings coincided more or less.

I am greatly indebted to Dr. J. H. Larkin, director of the pathological laboratories at the City Hospital, for the record of the autopsy protocols.

THE PREPUCE AS GRAFTING MATERIAL*

By I. C. Eisenberg, M.D.,

New York.

Even though plastic surgery is one of the oldest procedures in surgery, dating back to the ancient Hindus, this particular method of using the prepuce as grafting material has never before been recorded. Rhinoplasty was performed on Indians on whom the punishment of certain offenses as marital infidelity was cutting off the nose.[1] In 1450 Branca and his son Antonius were masters in restoring noses, they restored the nose of a man to such a perfect shape that his friends marveled at the change in their former friend.[2] In 1546 Tagliacozza, professor in Bologna, improved the Branca method and a little later published an illustrated volume describing his operative methods in rhinoplasty. In 1730 Sancassani relates an instance: a charlatan called Gambacurta, in Florence, peddling a certain ointment, in order to prove its efficacy, was accustomed to cut a piece of skin from her leg, pass it around the audience upon a plate, and then replace it in its original position, covering it with the ointment. Union took place so that the site of the operation was scarcely discernible.

John Bell[3] who was very firm in his belief that no portion of the body could grow on again after it has been completely removed, nevertheless, mentions an instance: the nose of a Spaniard

*From the Department of Surgery at the New York University and Bellevue Medical College.

wenty-nine years old was cut off and Fioravanti eplaced it and bandaged it. In two weeks it was eunited.

In 1869 skin grafting was made more certain, when J. L. Reverdin[4] before the Paris Société de Chirurgie claimed that bits of skin, severed from their original connections would dhere and grow upon a granulating surface. Many medical men of prominence sneered at the iscovery and greatly underrated its value, saying that such a procedure as skin grafting was ot likely to occupy a prominent position in minor urgery. Nevertheless in France, Reverdin's laims were soon abundantly established and skin rafting became very popular. Pollok[5] was among he first to adopt Reverdin's method in England, 870, he cites a few cases of skin grafting and he results obtained at the St. George Hospital.

Hand of B. S., showing finger healed with prepuce graft.

In 1871 Hodgen and Munoz[6] were two of the earliest writers on the subject in America.

At present plastic surgery is very widely practised and the principal methods are: Thiersch, Reverdin, Wolfe and Krause. In Thiersch's method long strips or shavings of same material are used. In Reverdin's method very small patches of the epidermis with the underlying upper layer of the derm are transplanted. These two methods are called Epidermatoplasty. In the Wolfe or Krause method large flaps from the entier thickness of the skin several square inches in size are used. This method is called Dermatoplasty. Grafting material has been obtained from the patient himself (autodermic), and another individual (heterodermic), and from animals (zoodermic). Grafts were obtained, almost from any part of the body and many methods are recorded, but of grafting from the prepuce the only case on record is that of Lucas.[7] He cites a case under his care at the Evelina Hospital which illustrates the value of prepuce grafting in children. Mr. Lucas took the prepuce of an out-door patient whom he had circumcised about half an hour previously and cut from it about twenty-eight grafts which he applied so as to form bridges across the wound. The patient was a two-and-a-half-year-old child who had been severely burned on the abdomen twelve days previous to admission. Lucas believed that the prepuce of a child possesses a germinal vitality, which renders it peculiarly serviceable for grafting. He also claims that preputial grafts will adhere when those from other parts fail. The following describes the use I made of prepuce as grafting material:

A boy sixteen years of age, who with several other boys was playing around a picket fence, climbed quickly to the top. In coming down he became entangled in the spikes. The point of one stuck between one of his fingers and a ring on it. He called to his playmates to help him down and they obligingly pulled at his feet. The tugging from below forced the spike into the finger and ripped off the ring, the last phalanx, part of periosteum of the second phalanx, and the skin down to the lower third of the first phalanx. Fearing to tell his parents, he wrapped his finger in a piece of rag picked up on an empty lot. When I saw him he had an infected wound, necrosis of the second phalanx, with a great deal of sloughing and destructive tissue. I amputated the necrosed part of the second phalanx by single external flap, there being no skin to form a covering. I waited till the wound became sterile (dichloramine-T treatment) and granulation had commenced. When it was fairly established, it was evident that transplantation of the skin would be of great service in hastening the cure and would doubtless save some secondary amputation.

Grafting being the only quick cure and not being able to get grafting material, I advised circumcision and the use of prepuce for grafts. On the thirty-eighth day after the accident, in the operating room of the college clinic, in the presence of Dr. B. Dubowsky and students, I made the wound aseptically clean, keeping the finger covered with a dressing of physiological salt solution while performing the circumcision; then, after having the prepuce emptied of blood, since blood remaining in the vessels is liable to clot and prevent the early resumption of circulation, I made a few button holes to allow free escape of serum and underlying air, pressed the graft firmly in place, all in one piece (like a finger stall), in order to remove the blood, bulbs of air, and as much moisture as possible. It was then dressed with Dakin's solution, a cotton wool bandage being applied firmly to insure close adaptation of the graft to the granular surface of the finger. On the fifth day the dressing was changed. There being a slight odor, I cut away some lazy parts and the wound, cleaned with Dakin's solution, was dressed again as at the first dressing.

Six days later, on removing the dressing, I noticed a line of cicatrization running from the circumference to the graft and from the graft to the open spaces. In sixty days cicatrization was complete and it has since remained so.

REPORT ON THE PREVENTION OF INFLUENZA.*

BY THE PUBLIC HEALTH COMMITTEE†
of
THE NEW YORK ACADEMY OF MEDICINE.

THE object of the Committee in considering the preparation of this report was a critical examination, for the benefit of the general practitioner, of the evidence that exists regarding methods of prevention of influenza and of guarding against the development of the pulmonary complications which often follow the initial infection.

In addition to surveying the literature, a special sub-committee held several conferences with men who, like Dr. William H. Park, Dr. R. J. Wilson, Dr. Dudley D. Roberts, Dr. Victor G. Heiser and Dr. Robert A. Cooke, had exceptional opportunity for studying the disease in its etiological and prophylactic phases, and they very kindly offered to the Committee their views on the subject under consideration.

The following is a summary of the evidence gathered:

Etiology.—While the exact etiological factors concerned in the production of the disease are still unknown, there is a good deal of clinical evidence in support of the view that the influenza infection is not due to the influenza bacillus alone, although this has been found to be present in a large proportion of the patients suffering from the disease. It appears likely that in addition there is another, an *x*-factor, the exact nature of which is still undetermined, which is possibly a filterable virus, and which initiates the infection and is responsible for a great lowering in resistance. This view is supported by the fact that consistent and very pronounced leucopenia is observed in all cases from the very beginning of the disease. This lowering of resistance appears to render the individual more susceptible to a secondary infection by a wide variety of organisms such as streptococci and pneumococci of various types, which are practically always to be found in the respiratory passages of most persons, and this secondary infection results in the production of the complicating pneumonia always present in the fatal cases. While there is much clinical evidence in support of such a view, sufficient laboratory and experimental research is not as yet available to prove it definitely.

Mode of Dissemination.—The strong probability that droplet infection plays a great role in the propagation of the disease is universally admitted, but experiments in the artificial production of the disease in human beings indicate that some additional factor, the nature of which is still unknown, is also concerned. This fact may account for the striking differences in the rapidity of the spread of the epidemic in various communities. Direct infection through contaminated hands, eating utensils, etc., is also a factor.

Immunity.—While the number of second attacks in individuals who have already recovered from the disease is very low, such cases do occur and there is no evidence that a single attack confers absolute immunity. Relative immunity, however, is produced. The fact that an epidemic completes its course within a certain time is the best proof, and an interesting light on this question is supplied by the fact that those who suffered most in the present epidemic were persons now too young to have had the disease in the epidemic of 1890. In this city the largest number of deaths occurred in persons 25 years of age.

One other important phase to be noted in this connection is that this disease, like malaria, has no predilection for those whose vitality has been lowered, but that the incidence is equally great among the strong and the weak.

Age and Sex Distribution.—There are no complete statistics as to the prevalence of the disease because of the failure of the physicians to report all cases of influenza. Mortality statistics offer the only reliable data. In New York City, from the beginning of October, 1918, to the end of January, 1919, there were over 27,000 deaths from influenza and pneumonia, of which 49.6 per cent. were male and 50.4 per cent. were female.

Children under 5 years constitute 15.5 per cent. of the total mortality.

Those between 5 and 15 constitute 5.7 per cent. of the total mortality.

The group from 15 to 25 constitute 17.4 per cent. of the total mortality.

The group from 25 to 45 constitute 47.7 per cent. of the total mortality.

The group from 45 to 64 constitute 10.1 per cent. of the total mortality.

The group of 65 and over constitute 3.6 per cent. of the total mortality.

As can be seen from the accompanying table, the monthly percentage with regard to age distribution of the several groups remained more or less stationary throughout the whole period. The only group whose relative percentage considerably decreased during December and January was that between 5 and 15 years of age. Likewise, contrary to the prevailing belief, the relative percentage of deaths among children under 5 years of age decreased during the last two months of the epidemic as compared with the month of November. The only increase in that group was among infants under one year of age. There was a decrease in the age group between 25 and 45 years, and more than a doubling of the relative percentage rate in the group over 65 years of age.

Preventive Measures. (a) General.—If the generally accepted theory of the dissemination of influenza be correct, preventive measures adopted to combat an epidemic must be of the same character as those in use for combating other infectious diseases spread in a similar manner. These measures

comprise restriction of droplet infection by guarding against coughing, sneezing, spitting, etc., prevention of contamination of the hands with respiratory discharges, the prevention of contamination of food and particularly the sterilization of eating utensils used by patients.

It is important that the public should realize that in taking precautions against influenzal infection, at the same time they are taking the necessary precautions against the definitely known causative factors of pneumonia and other respiratory diseases.

The study of the epidemiology of the disease emphasizes the great importance of the avoidance of overcrowding, especially among large bodies of people in barracks, institutions, etc. It has been shown that the incidence of these diseases varies in direct proportion to the degree of overcrowding of the groups of individuals so congregated.

(*b*) *Masks.*—In regard to the use of masks, it may be said that the reports from communities in which general masking of the population was attempted are wholly unsatisfactory as proof of the value or uselessness of the procedure owing to the different conditions under which the observations were made and the differences as to the stage of the epidemic at which the mask-wearing ordinances were promulgated.

It appears desirable, however, that those coming in contact with patients should wear masks for defensive purposes, providing these are suitably made and applied. If masks are used, it is essential that they be frequently changed and sterilized.

The possibility of droplet infection taking place through the conjunctival mucosa must also be kept in mind and means for preventing this by the use of goggles in some form are advisable.

While theoretically, the application of masks to patients is strongly indicated, the practical difficulties of insuring the proper wearing of the mask and especially of applying it to pneumonia patients whose respiration is already greatly embarrassed, render this measure of doubtful practical utility.

If masks are used, it is essential that they conform to standards which have been devised as a result of experiments proving the futility of relying on those improperly constructed. The experiments carried on by Doust and Lyons (*Journal A. M. A.*, October 1918, Volume 71, p. 1216) show that

1. During ordinary or loud speech, infected material from the mouth is rarely projected to a distance of 4 feet, and usually less. A 4-foot danger zone exists about the patient under these conditions.

2. During coughing infected material from the mouth may be projected at least 10 feet. The danger zone about a coughing patient has, then, a minimum radius of 10 feet.

3. Masks of coarse or medium gauze of from two to ten layers do not prevent the projection of infected material from the mouth during coughing. Such masks are worthless, therefore, in preventing the dissemination of respiratory infections.

4. A three-layer buttercloth mask is efficient in preventing the projection of infectious material from the mouth during speaking or coughing. It is a suitable mask, therefore, to be worn in connection with respiratory diseases.

(*c*) *Sprays and Gargles.*—Owing to the impossibility of rendering all the recesses of the respiratory passages free from bacteria, attempts at destruction of the infectious agent by the use of antiseptic sprays, gargles, etc., are illusory and efforts made to render carriers harmless by such means have been found unsatisfactory. Still a certain reduction of the bacterial flora can be effected and for this reason the use of mild, non-irritating sprays, washes, etc., carefully employed so as not to injure the mucous membrane, should not be discouraged.

(*d*) *Vaccines and Serum.*—Owing to our ignorance of the etiology of the disease, attempts at prophylaxis by the use of vaccines must still be regarded as being in the experimental stage. The attempts at combating secondary infections due to definite organisms such as streptococci and pneumococci by suitable vaccines offer much greater probability of success, and the numerous favorable results at hand show that efforts in this direction are to be encouraged.

The successful results reported in many cases by the administration of the serum of convalescent patients must be mentioned in this connection as very promising not only in the treatment but also in the prevention of complications.

(*e*) *Rest.*—Experience has shown very definitely that in times of an epidemic, putting patients to bed promptly on the first manifestations of any evidence of respiratory infection is of the greatest value in causing the disease to take a mild course and in preventing pulmonary complications.

(*f*) *Hospitalization.* — Hospital experience has shown definitely the value of isolation of patients. The fact that there has been a great deal of cross infection in hospital wards has led many institutions to devise mechanical methods aimed at checking the spread. The cubicle system or the still simpler method of separating patients from each other by linen screens eight feet high has proven to be of definite value. Such a procedure is particularly important in view of the evidence presented that when a case of virulent type is introduced in a ward of mild cases the majority of the patients very soon develop the virulent type of the disease if unprotected.

In order to avoid the spread of the epidemic in hospitals it is strongly indicated that the performance of operations be restricted during epidemic times to the absolutely urgent cases as evidence has shown that the conditions following operations conduce to the spread of the disease in the surgical wards of the hospital.

In view of the impossibility of providing adequate hospital facilities during an epidemc for all those requiring treatment it is urged that in mild, uncomplicated cases of influenza in which patients can obtain proper care at their homes, they should not be sent to hospitals.

DIETARY DEFICIENCY AND DISEASE.

PRACTICAL POINTERS ON HEALTH MAINTENANCE.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

DIETARY deficiency may result from various causes, or from a combination of causes, and it is the province of the physician to act as mentor or guide—to lessen sickness, to maintain the health standard, and to promote longevity.

That less than 60 per cent. of the draftees in the late war were available for military duty, and 85 per cent. of the volunteers for navy service were rejected for physical defects, is a sad commentary upon our modern civilization. And the rising generation gives no promise of improvement, one-third of all the school children in the registration area being from one to three years behind in their class standing, not to mention the rapidly increasing number of feeble-minded children, for whom special instruction must be provided.

The object of this communication is to afford physicians, parents, and the general public a practical method or working formula for regulating the dietary in accordance with normal demands and thus prove a safeguard against disease.

The essentials of the dietary, as well as the minimum required to support life and maintain a healthy activity of the various functions, have been determined with mathematical precision. They include protein, the rebuilding material, fats, and carbohydrates (sugar and starch) to provide heat and energy, together with mineral salts, sodium, calcium, or lime, magnesium, phosphorus, etc., these mineral substances being found in varying proportions in every tissue—bone, nerve, and muscle.

Deficiency of protein of good quality stunts the growth of children and adolescents, reduces the vitality of adults, and precipitates old age. Lack of fats causes loss of flesh, and without fats and carbohydrates starvation follows. Failure to obtain the minimum supply of mineral salts in the dietary for any considerable period is readily demonstrable by physical examination, because the deficiency upsets the chemical balance and deranges the nerve mechanism; nerve conduction is impaired, like the telephone mechanism after a storm.

In addition to the elementary substances composing our daily food materials there has recently been discovered, or rather demonstrated, certain vital "accessory" factors, which are believed to exercise an important influence upon digestion and assimilation. They are called vitamines, and there are at least two kinds or types. One is found principally in animal foods, and is soluble in fats; the other is found principally in vegetable foods, and is soluble in water.

Water-soluble vitamines constitute an important factor in the dietary, and should be conserved by saving the water in which vegetables are cooked, such as potatoes, peas, beans, spinach, etc. Their dietary value explains various occult theories in regard to certain food materials: that cabbage in the form of cold slaw was a valuable remedy against scurvy; that carrots, raw or cooked, were an essential dietary item in the case of kidney disorders; and that oranges would counteract the liability to neuralgia and neuritis. This merely goes to show why so many persons try to subsist upon a limited or restricted dietary, when it should be extended. Vegetable soup should be regarded as the essence of all vegetable foods. Mutton breast makes an excellent base for soups. It is palatable and nutritious.

Fat-soluble vitamines are less likely to be discarded or dissipated in the process of cooking, but a caution should be added relative to the dangers incident to soups prepared from the red meats, such as consommé, because they also carry the so-called purin bodies, now recognized as powerful nerve depressants.

Eggs, milk, butter, and cheese are especially rich in vitamines, also in mineral salts; and usually the leaf of a plant is found to be more effective as an "activator" than either the root or the seed.

Protein and Mineral Salts.—The protein molecule is the essential element in the living cell, the protoplasm. Upon its integrity depends the stability of reconstruction, also the maintenance of function and the defence against bacterial invasion, but without the presence of certain mineral salts its inherent properties are lost. Experimental investigations on small animals, rats, and guinea-pigs show that exclusion of protein from the dietary causes death from starvation, and that the absence of mineral salts stops reproduction within two or three generations; all evidence pointing to the demand for a liberal dietary, a "balanced ration" in respect to protein, fats, carbohydrates, mineral salts, and vitamines.

Practical Dietetics.—Without the advice and supervision of a physiological chemist there are few persons who could select the food materials containing all the requisite technical constituents necessary to supply the number of calories (heat units) demanded from day to day. Hence the need for a synopsis outlining a practical plan, a solution which

will enable any one of ordinary intelligence to modify and adjust the dietary, and the following method is suggested.

Food materials are conveniently divided into two main classes, animal and vegetable, with four subdivisions in each class:

Animal Food Materials.

1.—Mutton, lamb, poultry, ham, and beef with restrictions.
2.—Fish, all kinds.
3.—Eggs.
4.—Milk, butter, and cheese.

Vegetable Food Materials.

1.—Food from the seed—bread, peas, beans, rice, etc.
2.—Food from the leaf—lettuce, asparagus, cabbage as cold slaw, spinach, beet tops, etc.
3.—Food from fruit—apples, oranges, peaches, grapefruit, etc.
4.—Food from the root—potatoes, carrots, beets, parsnips, onions, etc.

Select for Breakfast.

Meats.—Mutton or lamb chops, fish of any kind, liver and bacon, frizzled beef, hashed corned beef, broiled ham.

Vegetables.—Potatoes, roasted, creamed, or fried with very little fat; bread, corn, wheat, rye, dry toast, milk toast; corn cakes, griddle cakes, but no hot bread, except rolls that have been moistened and thoroughly heated in the oven; boiled rice (unpolished). *No oatmeal or other cereal.*

Fruit.—Orange, grapefruit, cantaloupe, raspberries, strawberries, wineberries, stewed prunes, peaches (sliced or stewed), apricots, pineapple, sliced bananas or apples, any style if cooked.

Liquids.—Tea or coffee, with milk and sugar, if desired, but no cream; cocoa, water, or cambric tea; milk, cool or hot, with a little salt added.

No fluids should be taken to assist in swallowing the food; all liquids are to be taken at the end of the meal, and it is important that they be taken at this time to aid the digestion, and again about midway between meals, when the stomach begins to discharge its partially digested contents into the small intestine. *No ice-water* to chill the stomach and delay digestion.

Select for Lunch.

Meats.—Cold roast mutton, cold roast lamb, cold sliced ham, cold tongue, scrambled eggs, cold or frizzled dried beef, cold corned beef.

Vegetables.—Parslied potatoes with milk, fried potatoes with very little fat, roasted potatoes, or potatoes mashed and fried.

Liquids.—Tea, coffee, or water; milk, cool or hot, with a little salt added.

Select for Six O'clock Dinner.

Soup.—Vegetable soup, lamb soup, pea soup, mutton broth, chicken broth, tomato purée, asparagus soup, cream of celery soup.

Meats.—Roast lamb, roast or stewed chicken, roast mutton; fish, baked, boiled, broiled, or fried with very little fat; boiled ham, pot-roast of beef, the first water to be discarded at the end of an hour because it carries the so-called purin bodies, which are depressing to the nervous system.

Vegetables.—Potatoes, white or sweet, baked or boiled, stuffed potatoes; carrots, sliced and stewed; peas, beets, string beans, stewed tomatoes; onions, boiled or raw, or sliced with cucumbers; boiled parsnips, well done; spinach, cold slaw, lettuce, and tomato salad.

Fruit.—Rhubarb, apple sauce, baked apple, cranberry sauce, apricots, peaches, or jelly.

Liquids.—Tea, coffee, water, cool or hot—at the end of the meal, as much as desired, but *no ice-water* to chill the stomach and delay digestion, although there is no objection to a plate of ice cream if not eaten with cake.

1024 Walnut Street.

BACILLUS OR DISEASE; WHICH SHOULD BE TREATED IN INFLUENZA?

By Beverley Robinson, M.D.,
New York.

To-day, more even than previously, the younger physicians, especially those much given to laboratory work, attach, as it seems to me, too great importance to the presence of Pfeiffer's bacillus in influenza. It may be found, and often is, with general symptoms of grippal nature, and if so, the diagnosis is positively made of influenza. If not discovered, should the treatment be different? Personally, I do not think so. If the symptoms are mild, treat it judiciously, but without unduly alarming the patient or family. Frequently, in these instances, we have to do merely with an ordinary cold, and there is no reason to name it differently, except because influenza is stated to be or is prevalent.

But suppose the case starts out with very mild symptoms and suddenly becomes more serious, should we then reproach ourselves for not having affirmed in the beginning it would become so? I do not think so, if we have, as I said, acted judiciously; that is to say, given good general advice and suitable remedies. In no case is it advisable to give uncertain or injurious remedies. Such are, in my judgment, acetanilid, aspirin, antipyrin, phenacetin, except in very small doses. The first-named drug I positively eliminate from all useful medication.

Now, then, what about the bacillus, if it be present and found? Can we treat it directly, and with any known remedy? And if so, what would it avail? The bacillus in influenza simply stamps the nature of the disease; it has little or nothing to do with its gravity. It is the habitat of the poison, not the poison itself. It may be simply the scavenger who is there to be helpful rather than hurtful, in being inimical perhaps to other microbes which are injurious, in preventing their development.

Science may soon discover a thoroughly reliable protective or curative vaccine, or serum, in the treatment of influenza. Up to the present time it has not. Meanwhile, we must rely upon the best, most advised treatment we possess. If we have none that will positively and safely cure, we do have remedies which will ameliorate and lessen the se-

verity of influenza. What are these? Those like castor oil and sweet spirit of nitre, which have proved beneficial in very many cases, and surely did little or no harm. Among all the drugs with which I am familiar, as I have affirmed many times already, there is none quite equal to the salicylate of ammonium, given in the beginning of a cold, or influenza, in sufficient and frequently repeated doses. Of course, the giving of this remedy does not mean there should not be absolute insistence in every case upon observance of general rules of rest, diet, etc., which have been of known value to very many in my observation and that of all experienced practitioners.

SINGERS' AND SPEAKERS' SORE THROAT.

By JOHN J. LEVBARG, M.D.,

NEW YORK.

Every physician during the course of his daily work is confronted frequently with a very important subject and problem, namely a chronic sore throat, in those who use their voices a great deal.

This condition is a chronic catarrhal inflammation involving the mucous membrane of the pharynx and is commonly known as clergyman's sore throat. The disease is seldom localized in the pharyngeal wall only; but the nasopharynx is most commonly affected at the same time. This condition is invariably found in those who use their voices incorrectly. In most instances on examination you will find permanent changes in the deeper tissues of the pharynx, or in its glandular structure; also, there is found an altered secretion, resulting in a difficulty in using the pharyngeal muscles, thereby causing the constant symptoms of hoarseness and irritating cough.

An incorrect and improper method in breathing is the chief cause in the production of a chronic inflammation of the throat. On account of this improper breathing and lack of knowledge of the proper method of attack, the singer or speaker uses his muscles of phonation and the muscles of articulation incorrectly, thus causing an overtaxation of the pharyngeal and laryngeal structures. Also, on account of this increased action of the muscles, there is a great increase in the blood supply, and thus this continued abuse of the voice eventually results in changes of the deeper tissues, and leads finally to a relaxation of the walls.

Singers or speakers who use the voice outdoors force the volume of their voice in order that the people may hear or understand them. In straining to be heard they forget entirely the principles of the proper method of breathing and fail to attack the tones high and forward. A prominent opera singer came to me recently complaining of hoarseness and a slight hacking cough, also a tired feeling of the throat. On taking the history, I discovered that he was touring the country for the Liberty Loan, and performed mostly in the open air. He admitted that at times he forced his voice to a higher pitch so as to be heard over the noise of the audience. Examination showed a very dry membrane and a few enlarged follicles on the pharyngeal wall. Forcing and straining his voice caused his trouble. Rest and astringents to the pharynx and nasopharyngeal wall relieved him of the hoarseness and his cough. One enlarged follicle required the actual cautery.

The proper channel for admission of the air is the nose, and the use of the mouth for this purpose should be discouraged. The function of the nose in respiration is to warm the air and filter out from it dust and other matter which would cause irritation. Mouth breathing may be permissible when singing fast phrases and with very little time to rest, but continuous mouth breathing is a pernicious habit, causing dryness of the mouth and pharynx; the muscles tire easily, and a chronic inflammatory condition of the larynx may result; also the audition may become affected in mouth breathers. An absolute requisite for a singer or speaker is the sense of proper hearing.

The amount of air an individual takes in during ordinary respiration (tidal air) is about 1600 c.c. If we take in an additional amount over the tidal air (complemental air), it will be about 1500 c.c. more. Forced expiration (reserve air) is about 1500 c.c. The vital capacity is the amount which can be expelled by a forced expiration after taking a forced inspiration—3500 c.c. This proves to us that ordinary respiration (1600 c.c.) is not sufficient to control proper singing or speaking for any length of time, but by using the additional amount (complemental air), it will increase the power and the volume of the voice. Insufficient amount of air will cause straining of the voice. Straining plus incorrect attack and breathing causes clergyman's sore throat.

In clergyman's sore throat there is first an increased secretion of mucus and as the condition becomes worse the mucus begins to get sticky and tends to crust formation. The glandular tissue begins to hypertrophy and enlarged follicles and dilated vessels will be found on the pharyngeal wall. The voice becomes husky, and chronic hoarseness sets in. The singer or speaker loses control of his muscles and when he sings or speaks breaks will occur and he tires very easily. There is always a marked limitation of the voice and an inability to control the pitch.

In singing or speaking there is only one correct way of breathing and that is by the inferior costal diaphragmatic method. This method consists in having the inferior costals act in coordination with the diaphragm; the upper abdominal wall protrudes while the lower abdominal wall retracts; during the entire action the superior costal region or upper chest is held or fixed high. During expiration the individual must learn to control the emitted air—as expiration is a passive act.

The advantages derived from correct breathing and having control over the emitted air are many; in the first place the speaker or singer has the greatest amount of chest room, and a vast supply of reserve air; the singer or speaker develops perfect control of the expiratory air and the laryngeal muscles; he increases the range of his voice and retains the same quality throughout the so-called registers.

In treating this condition, drugs should be avoided as much as possible. This is not a disease caused by any specific germ, but is produced in singers and speakers by overtaxation and abuse of

the muscles of phonation. Absolute rest should be insisted upon; change instructors if a faulty technique of singing or speaking is present. Cold sponge to the neck in the morning, followed by massage, I find to be very helpful. In persistent large follicles the actual cautery may be used with impunity.

1425 Madison Avenue.

Medicolegal Notes.

Construction of Physician's Indemnity Insurance Policy.—In an action by a physician to recover upon a liability insurance policy, tried without a jury, the trial court concluded that there was no liability upon the policy. The plaintiff appealed. The facts were not in dispute. In 1911 the insurance company issued its policy, agreeing to indemnify the plaintiff, a physician and surgeon, "against loss from the liability imposed by law upon the assured, for damages on account of bodily injuries or death, suffered by any person or persons in consequence of any malpractice, error, or mistake—(a) of the assured in the practice of his profession during the term of this policy." Thereafter, while the policy was in force, on December 4, 1912, the plaintiff performed an operation upon one Michael Schuster, who thereafter brought an action against him, claiming that he failed to remove a gallstone which should have been removed in the course of the operation performed. In that action Schuster recovered a judgment for $2,466.15 and costs. The case was appealed to the Washington Supreme Court and the judgment affirmed. (Schuster v. Sutherland, 92 Wash. 135, 158 Pac. 730.) The plaintiff at the same time carried insurance in other companies, which paid their proportionate share of the judgment. This action was brought to recover the remainder against the defendant. It appears from the record in Schuster v. Sutherland that the plaintiff entered into an agreement with Mr. Schuster to remove all gallstones from the latter's body, and all cause of disease possible to be removed by a surgical operation; and that the plaintiff violated the agreement, failing to remove a gallstone. The trial court was evidently of the opinion that, because there was a special agreement to remove gallstones and to cure Mr. Schuster of the disease from which he was then suffering, this was not a liability insured against by the policy. The Washington Supreme Court holds this was error. If the damage was not caused by malpractice, it was held clearly caused by error or mistake in not removing the gallstone, and for that reason the damage was, in the Schuster case, assessed against the plaintiff. He was required to pay, and did pay, that amount for the error or mistake which he made in not removing the gallstone while in the practice of his profession.

It was argued that "the liability imposed by law" contained in the indemnity policy refers to common law liability only, and that a surgeon, under the law, is not required to enter into a contract, but is liable only for failure to exercise diligence, care and skill such as is ordinarily possessed by the members of his profession in good standing, and that when he made a contract to do more than that he took upon himself a liability not imposed by law. The court said this reasoning would no doubt be sound in case of malpractice on the part of the physician, but clearly the physician had a right to enter into a contract to remove all gallstones from the body of his patient and to effect a cure. He clearly had a right to do this in the practice of his profession; and if he made an error or mistake, or was guilty of malpractice, and damages resulted thereby to his patient, a recovery might be had. The words "malpractice," "error," and "mistake," as used in this indemnity policy, did not, it was held, mean necessarily the same thing. If they were so intended, it was an idle thing to insert more than the word "malpractice." A physician may err or make a mistake without being guilty of malpractice. This policy covered malpractice. It covered error, and it covered mistake in the practice of the plaintiff's profession; and if liability followed from either, and he was required to pay damages on that account, the court thought it plain that the policy undertook to insure against such mistake or such error, as well as against malpractice.

It was held that the words "liability imposed by law" clearly refer to a judgment recovered on account of malpractice, error, or mistake, and did not limit the policy to cases where there was simply malpractice, where the physician is required to use care, diligence, and such skill as is ordinarily possessed by the average members of the profession in good standing. The judgment in the Schuster case was a liability fixed by law. This liability resulted from an error or mistake of the plaintiff in his treatment of Mr. Schuster. The mere fact that the plaintiff had a special contract to remove all of the gallstones from Mr. Schuster did not affect the insurance policy, because it was a contract made in the practice of the plaintiff's profession, and one which he clearly had a right to make. The result was that he failed to remove the gallstones, and therefore failed to cure the patient, as he had agreed to do, and damages resulted, which he was required to pay. The court was therefore of opinion that the policy covered the liability, and that the plaintiff was entitled to recover the balance which he was required to pay under the judgment, which, according to the evidence, was $1,603.33.—Sutherland v. Fidelity & Casualty Co., Washington Supreme Court, 175 Pac. 187.

Death from Germ Infection.—In a proceeding for compensation for the death of a woolsorter from anthrax the principal question was whether the death was the result of an accident happening to him during the course of his employment. The employer admitted that the deceased died of external, and not internal, anthrax. The findings of the referee showed accord among the doctor that, in the majority of cases, the inoculation which causes external anthrax occurs through a scratch or abrasion of the skin; while internal anthrax is usually caused by inhaling the germ, or taking it in food.

The findings further showed that when the deceased went to his work on the morning of April 4, 1916, he was perfectly well and had no abrasion or mark upon his neck, but when he left the plant, in the afternoon, there was a "little scratch" or abrasion, "about the size of a dime," just above the Adam's apple, which caused a swelling, and that this was the beginning of external anthrax, from which he died within three days. The findings likewise showed professional medical experts testified that, in their opinion: "If deceased was a woolsorter, when he went to work on April 4, 1916, with no marks on his neck, and sustained an abrasion about the size of a dime upon his neck, and the neck immediately began to swell, and external anthrax developed, this condition probably was brought about by the anthrax germ entering through the abrasion." The court held that, under the circumstances of the case, the deceased apparently not having been where he was liable to become inoculated with external anthrax except at his work, and he, as he left the defendant's mill on the day in question, having shown symptoms of that disease by the mark upon and swelling of his neck, the inference might reasonably be drawn, in view of the nature of the work on which he was engaged, that the inoculation occurred during the course of his employment.

The court added that, when death results from germ infection, in order to bring a case of this character under the act of 1915, the disease must be a sudden development from some abrupt violence to the physical structure of the body, and not the mere result of gradual development from long-continued exposure to natural dangers incident to the deceased's employment, as in the case of occupational diseases, the risks of which are voluntarily assumed. Here the anthrax germ, a distinguishable entity, came into actual contact with the deceased, thus gaining an entrance into his body, and his neck began to swell and discolor; therefore the complaint from which he died could be traced to a certain time when there was a sudden or violent change in the condition of the physical structure of his body, just as though a serpent, concealed in the material upon which he was working, had unexpectedly and suddenly bitten him. Judgment reversing a decision of the compensation board setting aside the referee's award of compensation was affirmed.—McCauley v. Imp. Woolen Co., Penn. Supreme Court, 104 Atl. 617.

Military Medicine.

Medical Service Corps to Dissolve.—The Volunteer Medical Service Corps, with its membership of more than 56,000 physicians, will dissolve on April 1. The names of all the physicians will be turned over to the Surgeon General of the Public Health Service, and will thus be accessible, if need for their services should arise in the future. Dr. Edward P. Davis, president of the corps, in commenting on the work of the corps in caring for civilian health during the war, and in aiding medical branches of the military service, characterized it as "a very striking demonstration of the American spirit."

Navy Puts Men in Good Physical Condition.—Figures recently compiled by Lieut. F. L. Ridge of the Naval Medical Corps for the bureau of medicine and surgery of the Navy Department shows that men are returned to civil life in much better condition than when they entered the service. Lieut. Ridge has examined 500 men leaving the service, and reports that the average result was a gain of 1¾ inches in chest measurement, an increase of 5.3 pounds in weight, enlargement of the biceps by ¾ inch, and reduction of the waist line by ¾ in. The greatest individual increase recorded was in the weight of a landsman machinist's mate, aviation, who enlisted at the age of seventeen years, and after a year in the service is leaving 52 pounds heavier.

Suicides in Army.—The War Department publishes statistics showing that from the date of entry of the United States into the war, to February 21, 1919, there were 339 suicide cases in the army. Of these, 193 occurred in the United States and 146 overseas. This is far below the average in civil life during the years 1914, 1915, and 1916.

Influenza Disappears from Camps.—Influenza has practically disappeared from the majority of the army camps of this country, and the general health of the troops, both at home and abroad, continues to show improvement. Pneumonia, which is reported as declining among the home troops, continues to be the prevailing disease among the expeditionary forces, 1,337 cases being reported for the week ending March 19, against 1,942 for the previous week.

Capt. Cassell Tucker, M.C., U.S.A., of Jamaica Plain, Mass., who has been on detached service with the British forces, was invested with the Military Cross by King George at Buckingham Palace, on March 20.

Capt. Charles B. Gibson, who has been serving with the Red Cross in Bulgaria, recently arrived in this country.

Deaths in the Service.—Lieut. William Benjamin Jones, M. C., U. S. Army, of Rochester, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1884, died suddenly in his automobile, on March 1, at the age of 57 years. He was consulting surgeon to the Willard State Hospital, and the Craig Colony for Epileptics, and surgeon to St. Mary's Hospital, Rochester, N. Y.

Lieut. James J. Beaton, M. C., U. S. Army, of Waycross, Ga., a graduate of the Atlanta, Ga., School of Medicine, in 1909, died at Camp Merritt on February 8, aged 31 years.

Lieut. Thomas Goodglick, M. C., U. S. Army, of Seattle, a graduate of the College of Physicians and Surgeons, New York, in 1916, died from pneumonia, following influenza, while on duty with the Aviation Section at North Bend, Ore., on November 8, aged 25 years.

Lieut. Charles Edgar Holbrook, M. C., U. S. Army, of Montreal, Quebec, a graduate of McGill University, Montreal, in 1908, died at the Royal Victoria Hospital, Montreal, on October 18, 1918, aged 33 years.

Lieut. Frank Martin Dedaker, M. C., U. S. Army, of Gloucester City, N. J., a graduate of the University of Louisville, Ky., in 1910, died from pneumonia, following influenza, at his home, on October 6, aged 31 years.

Lieut. John Leon Kerr, M. C., U. S. Army, of Hazlewood, Pa., a graduate of the University of Pittsburgh, in 1912, died from bronchopneumonia on October 27, 1918, aged 31 years.

Lieut. Clarence Edward Farrish, M. C., U. S. Army, of Mobile, Ala., a graduate of the University of Alabama in 1906, died from injuries received in a collision while driving his automobile over a grade crossing at Brewton, Ala., on February 20, aged 36 years.

Capt. Hyman Caro, M. C., U. S. Army, of Chelsea, Mass., a graduate of Harvard Medical School, in 1914, formerly on the staff of the Monson State Hospital, Palmer, Mass., on duty with the American Expeditionary Forces, died at Mars, France, on January 22, from bronchopneumonia, aged 29 years.

Capt. John Eberly Kuykendall, M. C., U. S. Army, of Eugene, Ore., a graduate of Cooper Medical College, San Francisco, in 1912, in command of the 361st Ambulance Company, A. E. F., died from meningitis in LeMans, France, on February 22, aged 33 years.

Capt. Robert Boyden Znderwood, M. C., U. S. Army, of Memphis, Tenn., a graduate of the University of Nebraska, Omaha, in 1904, died in the American Red Cross Hospital at Rouen, France, on November 12, from pneumonia. He was district surgeon of the Illinois Central, and Yazoo and Mississippi Valley Railroad, and formerly captain in the medical department of the National Guard of Tennessee. During the war he was commanding officer of the 118th Field Hospital, 105th Sanitary Train, Thirteenth Division, and also in charge of the advanced dressing station.

Capt. Walter Henry Fox, M. C., U. S. Army, of Waucoma, Iowa, a graduate of the University of Iowa, Iowa City, in 1905, died from septic pneumonia, in Serbia, on February 22, aged 35 years. He was assistant professor of anatomy in his alma mater, served at Base Hospital No. 85, in Paris, until January 18, when he was transferred to the Balkan Commission and sent to Belgrade.

Lieut. Samuel Harold Boyd, M. C., U. S. Army, of Philadelphia, Pa., a graduate of the University of Pennsylvania, in 1913, died in the Base Hospital at Camp Merritt, N. J., from valvular heart disease, on December 24, aged 30 years.

Capt. Hugh Frank Taylor, M. C., U. S. Army, of Mintonville, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1893, died from chronic diffuse nephritis while on duty at Camp Mills, N. Y., on December 18, aged 47 years.

THE DIAGNOSIS OF THE OCULAR PARALYSES IN CEREBROSPINAL MENINGITIS.

IN a general way it may be said that the ocular paralyses met with in epidemic cerebrospinal meningitis are transitory and are recovered from during the decline of, or convalescence from the disease, and even when they persist they become attenuated in a remarkable way. The benign character of their prognosis is, consequently, one of their foremost characteristics and is explained by a process of perineuritis. The paralyses of accommodation are not usually an exception to this rule, but, nevertheless, two varieties are to be distinguished, one being early in onset, benign, and undergoing its evolution toward complete recovery in a few days, the other occurring late in the affection, being much more serious, and lasting for several weeks. In certain cases a chronic neuritis succeeds the inflammatory process in the nerve trunks and the paralysis becomes a sequel of the meningitis, but when a comparison is made with ocular paralysis as a sequel and other sensorial complications, it becomes at once evident that it is rare.

A positive diagnosis of an ocular paralysis is based upon the well known subjective and objective symptoms and is difficult in only two circumstances. The first is when the paralysis is very attenuated, to such an extent that a deviation of the globe is not apparent and the gaze simply appears indeterminate and the side on which the strabismus exists cannot be determined, all the more so because diplopia is not always complained of. The patient unconsciously corrects the deviation and merely suffers ocular fatigue and periorbital pain after reading. In these circumstances the limits of ocular excursion in all directions should be sought for. Secondly, when the paralysis involves both oblique muscles the fact is difficult to detect on account of the complex action of these muscles. This paralysis is undoubtedly infrequent as an isolated lesion in cerebrospinal meningitis.

The differential diagnosis is devoid of any great difficulty and it is probable that an external ophthalmoplegia will not be mistaken for congenital strabismus, in which there is no diplopia or limitation of the movements of the globe, while the secondary deviation is not more pronounced than the primary.

The diagnosis of the seat of the lesion resulting in ocular paralysis of cerebrospinal meningitis is interesting from many points of view. Usually it is at the base, that is to say, due to lesions of the nerve along its track from the base to the skull. When the third pair is involved no paralytic dissociation will be noted between the external and internal musculatures of the eye, although this rule suffers a number of exceptions. The paralysis may also be caused by a lesion of the nerve in its orbital portion, involving only some isolated ramifications, or, on the other hand, the entire internal and external musculatures may be compromised. In these circumstances paralyses due to trauma, fracture, or orbital new growths must be eliminated. In the latter lesions an exophthalmus, venous stasis, edema of the lids, and sensitive disturbances in the domain of the ophthalmic branch of Willis are prone to exist.

Nuclear paralyses are characterized by a progressive, bilateral involvement of the various muscles indirectly belonging to the three nerves of the eye, as well as by a systematization of these paralyses which respect the internal musculature even when all the motor muscles of the globe are involved. Finally, certain nuclei are united by anastomoses with those of the synergic muscles of the opposite side, in which case an associated paralysis results. Thus the nuclear paralyses of the sixth pair will invariably be associated with a paralysis of the internal rectus on the opposite side.

A meningitis of otogenous origin may produce ocular paralyses involving especially the external ocular motor muscle, but in otic paralyses there will be a history of ear trouble and pressure over the mastoid process will be painful. However, it must not be forgotten that an otitis may be overlooked. A tuberculous meningitis has a subacute or chronic evolution and lumbar puncture will give a decisive result, so that no difficulty will be experienced in making a diagnosis of the nature of the ocular paralysis when due to this affection.

AMBROISE PARE ON EPIDEMICS.

THE "father of surgery" had a wide experience with the pestilential diseases which follow often in the wake of wars, and this experience, together with his medical horse sense, make his comments of value even today. As a surgeon he knew sepsis when he saw it, and the fact that the epidemics were medical and not surgical infections did not confuse him. He accused indifferently as causal factors bad food and water, cadaveric emanations, an animal factor (synchronous infection of domestic animals), fomites, etc. He was no believer in typical epidemics—rather there was a congeries of different symptoms in these visitations. He dwelt on the dark color of the skin as of diagnostic and prognostic significance—this evidently being the source of the terms "black death," "black plague," etc. But, as stated, he was no absolute unicist,

and the plague or pest was not altogether one affection, but the sum of all. Plicqué, who has made these extracts from Paré's works for the *Journal de médecine et de chirurgie pratiques* of February 10, asks whether this conception of a pandemic pestilence might not hold good today for influenza. In Paré's time there were complaints of sophisticated bread, of spoiled wine, and tainted water, of diseased cereals, etc. In 1566 bread was made of almost any vegetable product which contained nutriment, and an increase of disease was noted at the same time. Under bad drinking water were comprised such supplies as were contaminated with sewage, or had been used for laundry purposes. Water fouled with the excreta of pestilential victims was especially dangerous. Under bad air was comprised air naturally unhealthy, as humid or hot air, which was the more readily corrupted by emanations from pest victims and cadavers. There were during these plagues many unburied and decomposed carcasses of both men and animals, while other cadavers were buried very superficially, so that the soil was to be thought of as contaminated.

According to Paré the pestiferous air was bad for vegetation, with the result that the crops were inferior, the cereal grains subject to various diseases, and the domestic animals infected—some apparently from eating carcasses unburied or buried superficially. These were especially stray dogs and cats, and Paré would destroy such. Bedbugs and fleas were numerous, but rats are not mentioned. For Paré a pestilence was the sum of all of the individual lesions of cumulative incidence—putrid fevers, dysentery, catarrhal affections, cough, quinzy, pleurisy, peripneumonia, lethargy, purpura —all of which may accompany influenza—and apoplexy, smallpox, ophthalmia, measles, anthrax, and other forms of malignant postule. Differentiation is impossible, for, however different the individual manifestations, all bear a common stamp of a single pestilence. This remark is especially significant of the pandemics of influenza.

While Paré's account does not seem to apply very closely to the bubonic and lung pest, the black coloration is mentioned as of great importance in both diagnosis and prognosis. Historians have differed as to the nature of the blackness of black death. Was it ecchymotic, was it cadaveric discoloration appearing before death, was it gangrene, or, finally, was it cyanosis? It could well mean all four, but whatever else it was, the cyanotic element must have been present. Paré mentions the black or livid discoloration of the nose, ears, and nails, also the tongue, which could only have referred to cyanosis. On the other hand other discoloration may well have meant purpura and ecchymoses. Other black areas not known in influenza may have meant gangrene, for lesions like malignant pustule seem to have been common, and extensive gangrene *en masse* was also seen. The belief that the infectious matter lingered in furniture and drapery led to attempts at disinfection. The prophylactic measures advocated were not so drastic as those recommended for the bubonic plague, for there is no mention of strict quarantine nor of burning infected dwellings nor any advice to leave the city. Paré thought a man stood a better chance by remaining in Paris.

SCURVY.

DURING the spring of 1918 an outbreak of scurvy occurred among the African natives who were working on the lines of communication in France. This outbreak and its sequelæ are of much interest so far as the causation of scurvy is concerned and add additional evidence, if such were needed, to the claim that it is a deficiency disease. Captain Hamilton W. Dyke, R. A. M. C., who reported this outbreak in the *Lancet*, October 9, 1918, stated that the ration of these men was ample and varied and included 8 ounces of vegetables. The author had four companies of 450 men each under his charge. The symptoms of the attack were myalgic pains, gingivitis, hemorrhages into muscles, usually of the calf, petechial hemorrhages into the hair follicles of the legs, roughness of the skin between the knee and ankle, anemia, and occasionally fever. The outbreak was attributed to (1) inability to supplement the diet now and then with extra fresh fruit and vegetables, and (2) reduction of the antiscorbutic value of the vegetables by excessive cooking; it was the custom to boil them for about two hours. This period was reduced to forty minutes, and fresh fruit and vegetables (*e.g.* carrots to be eaten raw) and a mildly alcoholic native beer prepared from germinated grain were provided. It is to Kaffir beer that the author attributes the absence of survy in the Kraals in winter when vegetables are not to be had. There is no doubt that the scurvy among these natives was due to a lack or absence of the antiscorbutic vitamines in the food.

Some very instructive facts regarding the prevention and treatment of survy have been disclosed recently. For instance, Dr. Harriette Chick, Miss E. Margaret Hume, and Miss Ruth F. Skelton published in the *Lancet* for November 30, 1918, a paper in which it was shown that fresh lemons were superior by far to limes with respect to antiscorbutic properties and Dr. Chick and Miss Hume in a paper contributed to the *Journal of the R. A. M. C.* for August, 1917, demonstrated that germinated pulses are richly endowed with antiscorbutic vitamines. Moreover, beer made from fresh germinated barley possesses marked antiscorbutic properties. The Kaffir beer is a thin fermented gruel made with a germinated millet. Beer manufactured by modern methods of malting and brewing does not contain the antiscorbutic vitamines, otherwise it might be brought forward as an argument against prohibition that beer was a means of preventing a deficiency disease. That dry beans develop upon germination remarkable antiscorbutic properties is information of much value, for these are cheaper and easier to procure than fresh lemons or fruits.

All fresh fruits, vegetables, and roots contain the antiscorbutic elements in varying amounts, but as these are very sensitive to prolonged drying and heat, an exclusive diet of canned or even too rapidly dehydrated vegetables and fruit is apt to produce scurvy. These accessory factors of diet, the vitamines, exert an immense influence upon growth and nutrition. Without them or with an insufficient quantity of them a diet is ill balanced and normal growth cannot go on nor will bodily weight be maintained.

SOME LATE MANIFESTATIONS OF RICKETS.

Localized manifestations of rickets occurring tardily comprise, in the first place, the so-called essential scoliosis of young girls although this is met with in boys as well. This variety of scoliosis can be explained only by some change in the vertebræ. Vicious attitudes, prolonged immobility, and unilateral debility of the muscles of the back, which have been invoked as essential factors, play only a secondary part and it is beyond a doubt that the scoliosis is the most frequent manifestation of late rickets. Genu valgum of adolescence, usually unilateral, is likewise due to late rickets, while the pes valgus of young people is occasionally due to the same cause. This also applies to a deformity of the clavicle met with in children and adolescents, consisting of a swelling of the internal end of the bone with subluxation of the sternoclavicular joint. It frequently coexists with scoliosis or genu valgum. Certain lordoses of adolescents have been attributed to late rickets, the curve being usually seated over the first and second lumbar vertebrae. To it may be attributed the cause of orthostatic albuminuria, which often coincides with late rickets, because when the subject is in the erect position the lordosis causes a compression or bend of the renal vessels so that an albuminuria results from the stasis thus produced.

Late rickets is responsible for a deformity of the wrist which has been variously termed progressive subluxation of the carpus, carpus curvus, or radius curvus, and again carpokyphosis. It is a primary deformity of the lower end of the radius which becomes incurved forward and inward as a result of a rachitic change in the cartilage. From this there results a forward projection of the carpus having the aspect of a subluxation, while in other cases there is a true subluxation of the lower radioulnar joint, with a prominence on the back of the wrist caused by the end of the ulna. The deformity hinders the wrist movements, especially extension. It is more common in young girls and may be hereditary. Late rickets is sometimes responsible for coxa vara in young boys, which may be unilateral or bilateral. In the latter case the left hip is always the more involved of the two and in unilateral cases the left hip is more commonly the seat of the trouble. It is more than probable that coxa valga is not infrequently the result of a rachitic process.

The localized manifestations of late rickets may be completely isolated or coexist in pairs or even in threes in the same subject, one of them being more accentuated than the others. Thus a scoliosis of an advanced type will be encountered in a subject presenting a mild degree of genu valgum or flat foot. While deformities of the knee are especially frequent in boys they are occasionally met with in girls, but on the other hand the latter represent the largest number of scolioses. Pathology teaches us that there is not merely a lateral inclination but also a torsion in these cases. The lateral inclinations might be explained by the simple mechanical action of weight, as is admitted for purely static scoliosis, but the rotation around an axis passing through the vertebral plates united by the yellow ligaments, cannot be explained otherwise than by an unequal development of the vertebral bodies. The question therefore arises as to what may be the primary cause of this irregular growth of the spine. The classical treatises on anatomy state that the vertebrae do not attain their final dimensions before the twentieth to the twenty-fifth year of life. Between the ages of thirteen and eighteen years the vertebral bodies are the seat of an energetic process of growth around complementary osseous points appearing at this age in the form of thin lamellae on the upper and lower surfaces of the vertebral bodies.

The reason why rachitis tardily arises in young girls is not a mystery. At the time the menses become established anemia or chlorosis is apt to appear, while the attendant weakened condition easily provokes rickets, one of the forms of impaired nutrition long since described by that great master of general pathology, Bouchard.

Overtures from German Scientists.

The Universities of Leipsic and of Heidelberg recently sent a letter to all the French Universities suggesting that, now the war was practically over, the pre-war relations between the universities of the two countries be renewed. Some of the institutions addressed made no reply; others bluntly refused to pick up the threads where the Germans had savagely cut them. The University of Bordeaux wrote as follows: "Please make a short visit to the devastated regions of Northern France and then inform us upon your return how long it would be before you would renew relations with a people committing similar deeds in your country. The generation perpetrating such abominations has severed all connection with humanity. Perhaps we shall renew relations with the next generation." We wonder how many lessons of this sort will be necessary before the Teuton mind realizes that rape and rapine are not innocent pastimes to be indulged in with impunity whenever the war lord permits. The German professors who signed the proclamation accepting responsibility for all the abominable atrocities decreed by the Emperor and the General Staff are now complaining of the unbrotherliness of the British and French scientific societies in dropping them from honorary membership, and appear to look for early rehabilitation and renewal of fellowship. We hope there will be some authoritative expression of opinion by the American profession, when the American Medical Association meets next June, re-

garding the attitude to be maintained toward the profession in Germany and the individual members of it who purpose coming here to practise as soon as they are let.

Eradication of the Mosquito and Malaria Control.

The general public has benefited considerably by some of the measures initiated in the first instance with the view of safeguarding the health of the men in cantonments and of those working in munition factories and in other places of military importance. Especially have the means taken to eradicate mosquitos been of service to the general health. Both the Army Medical Corps and the Public Health Service have been engaged in this work and the results have been satisfactory. In general the principles of mosquito control used in the extra cantonment sanitation, that is, the methods employed by the Public Health Service, have been those used effectively in the Canal Zone. These are fully and graphically described by C. W. Metz, special investigator of the Service, in the Public Health Reports for January 31, 1919. These methods consist primarily of drainage and oiling, drainage where the water can be disposed of, and oiling where it must remain. Drainage is the most reliable and permanent method of control—no water, no mosquitos. Since all these measures are aimed at the destruction of Anopheles larvæ, attention should first be directed to the general conditions necessary to accomplish this object. As is pointed out, the methods are simple, but upon the proper choice of methods may depend many lives and thousands of dollars. For example, Anopheles larvæ will not develop in a locality if (1) The water is completely drained off; or (2) the water surface is entirely cleared of vegetation or other obstructions, the banks cleaned and cut down vertically, giving a smooth margin; and (*a*) an abundance of suitable fish made available to keep down the larvæ; or (*b*) a complete film of oil applied to the entire surface; or (*c*) a swift flow of water set up to carry off the larvæ or prevent their feeding; or (3) the water is treated with an effective larvicide. As said before, one or other of these measures has been carried out in the zones surrounding cantonments, which means that the work has been very extensive, and its beneficial influence will be doubtless exhibited in a large decrease of malaria among the civilian population.

Galen on Simulation.

In *Il Policlinico* for January 5, Bilancioni quotes this ancient authority on feigned diseases. There are many reasons, said Galen, why men counterfeit various illnesses. Hence the medical men should be able to distinguish between bona fide and assumed illness. Phlegmons and erysipelas may be counterfeited and also edema. Blood from the mouth may appear as if it came from the lungs. The simulator first has a paroxysm of coughing, at the end of which blood sucked from the gums is spat out. Pain is, of course, the easiest to feign and the hardest to detect. In the case of a man seized in public with an alleged attack of colic the surgeon, if he suspect him, may accuse him of lying or order cold applications. In one case the motive in claiming to suffer from colic in a crowded place was evidently to obtain material aid; Galen accused the man of faking and he later admitted it. If the man be really in severe pain he will at once accept any suggestion for treatment and, vice versa, will show timidity if he is shamming. Colic also depends on the mode of living, on exposure or other efficient cause, and in simulators no such causes can be elicited. In a youth who simulated a painful knee Galen found that there was a girl in the case, and that the youth would have had to make a long journey with his master and be separated from her. The knee was indeed swollen but Galen found the condition was an artifact due to the application of some irritant drug. Other simulation is brought about by fasting and the internal use of powerful drugs. Galen wrote at much length on the entire subject of simulation and perhaps nothing in his writings, extensive though they be, gives us a truer idea of his real claim to sagacity and resourcefulness and to a certain medical horse sense which the grotesque theories of his time could not mask.

Coffee in Strangulated Hernia.

At rare intervals cases have been cited in which the use of caffeine or simply coffee has apparently been of value in the reduction of strangulated hernia. Naturally it is associated with localities remote from hospitals. This treatment is by no means new, and as far back as 1857 a case was reported in *El Siglo Medico*. A man of thirty-eight, who wore a double truss for hernia, suffered from strangulation on one side after a powerful muscular effort. Taxis was of no avail, and the patient was suffering much pain. An octogenarian practitioner who was present mentionad an odd but sovereign remedy in use in Havana, which he had seen to be efficacious on many occasions. Invited to test it, he ordered hot black coffee with but little sugar, one cup every quarter hour. After the fifth cup there was a rush of air heard, and after the ninth the hernia was spontaneously reduced. The publication of this case led to a second report in the *Bulletin de thérapeutique* in which two favorable results of the same class are given, both patients being old women. The strangulation had followed removal of the truss. After two and four cups respectively the hernia reduced itself spontaneously.

News of the Week.

Diphtheria Gains Ground in Sing Sing.—Reports from Sing Sing Prison, which is now quarantined because of a diphtheria epidemic, state that up to March 17 there were 65 cases, 25 of which were reported during the last twenty-four hours. These, together with those suffering from influenza and other diseases, brings the number of patients in the prison at the present time up to 115.

State Hospital Inmates Vaccinated Against Pneumonia.—The United States Public Health Service, cooperating with the New York State Hospital Commmission and the State Department of Health, has vaccinated approximately 19,000 in-

mates of State hospitals against pneumonia. The object in extending this form of vaccination to the inmates of State institutions is to ascertain if the method is as effective in these institutions as it has apparently been among the military and naval forces.

Diagnostic Hospital Plans.—The New York Diagnostic Hospital, at No. 125 West Seventy-second Street, will be opened the first week in May. This institution, the first of its kind in this country, has been made possible through the work of more than one thousand physicians, who have raised the necessary funds. At present the hospital will be for diagnosis only, and about 500 cases for special diagnosis can be accommodated daily. The new hospital will represent an outlay of about $500,000, all of which has been pledged but about $90,000. Among the physicians especially interested in the work are Dr. Robert T. Morris, Dr. Thomas E. Satterthwaite, Dr. Abraham Jacobi, and Dr. M. Joseph Mandelbaum, the latter being President of the Board of Directors. Plans are being considered for the erection in the future of two ten-story buildings on either side of the present building which will be able to accommodate 400 patients for operation and study.

To Open Three New Maternity Clinics.—The New York Milk Committee, in line with its plans for extending its prenatal nursing, and infant welfare work, has formally opened three additional maternity clinics in the Bronx. These clinics are located at the Bronx House, 1637 Washington Avenue, and at the Baby Health Stations at 2389 Hughes Avenue and 513 East 149th Street.

Anti-Prohibition Resolutions.—At a meeting of the Homeopathic Medical Society of the County of New York, held March 13, the following resolution was passed:

Whereas, An amendment to the Constitution of the United States calling for the total abolition of the use of alcoholic beverages is now on the eve of enforcement;

Resolved, That this Society, while recognizing the great evils both physical and moral which are due to the abuse of alcoholic beverages, regards the enactment of such a drastic measure as not conducive to the welfare of the public, as it does not solve the problem of the evil of the abuse of alcoholic beverages and will tend to other evils. Furthermore, disastrous results from an economic standpoint appear inevitable, the time most inopportune, and the invasion of personal liberty and rights evident.

Postgraduate Courses in Neurology have again been resumed at the Neurological Institute, New York City. Any graduate in medicine with proper credentials may be admitted to these courses. There is no actual time limit to the length of the courses though a minimum of six weeks is advised.

Influenza Again Epidemic in Brazil.—A despatch from Sao Paulo, Brazil, under date of March 16, reports that influenza has again appeared in epidemic form in that country. The Government is taking measures to prevent the spread of the disease.

English Death Rate Exceeds Birth Rate.—For the first time since the establishment of a system of registration the death rate has exceeded the birth rate in England and Wales in the last quarter of 1918. According to the report of the Registrar General the births during this quarter numbered 161,775 and the deaths 241,218. The deaths exceeded those of the preceding quarter by 127,000. Influenza was found to be either the primary or contributory cause of no fewer than 98,998 deaths in the last quarter of 1918.

Protests Against Davenport-Donohue Bill.—A general meeting of Harlem physicians was called at the rooms of the Harlem Board of Commerce in response to an invitation from that body, on March 5, 1919, for the purpose of discussing the proposed Compulsory Health Insurance Bill now before the Legislature. As a result of the discussion resolutions were adopted which, while expressing neither approval nor disapproval of the general principles of Compulsory Health Insurance, disapproved of certain features of Assembly Bill No. 90, known as the "Health Insurance Law," as partaking of class legislation and inequitable alike to the medical profession and those who would be beneficiaries under this law. The resolutions point out that the bill makes provision only for those steadily and lucratively employed, with no provision for the medical relief of the indigent poor, and that the tendency of the bill would be to increase rather than diminish the number who must seek relief through our hospitals, dispensaries and charitable institutions. From the standpoint of the medical profession, the resolutions point out that the bill denies the insured the right to select his own physician, that physicians are entirely excluded from the councils of the administration and denied membership in the Board of Directors, and are thus without voice in fixing fees or making contracts. The resolutions suggest several amendments which would remedy these defects, among them being one providing that every physician in good and regular standing shall at all times be a member of the local panel so long as he shall honorably and conscientiously continue to practise his profession. The resolutions also call for a Board of Directors comprised of seven members, two of whom shall be physicians. The Harlem Board of Commerce passed resolutions endorsing those presented by the physicians, and expressing the opinion that a Health Insurance Law was not demanded from an economic standpoint by either business or social interests.

At a hearing on the Davenport-Donohue Bill, on March 19, Senator Davenport announced that he had amended the bill to meet some of the objections made by physicians. Chief among the changes is a provision that the head of the proposed bureau of health insurance shall be a physician, and that beneficiaries shall be permitted to select their own physician. Another amendment provides for a more equitable arrangement in regard to fees. At the hearing the bill was opposed by merchants, manufacturers, physicians, and representatives of fraternal orders. Those supporting it were spokesmen from the labor unions and women's organizations.

According to announcement made by the Women's Joint Legislative Conference and the State Federation of Labor, the organizations sponsoring the Health Insurance Bill, this measure will be amended to meet many of the objections voiced by the medical profession. One of the amendments provides that

physicians will not be on a salary, but will be paid according to services rendered under a schedule of fees to be approved by the State Industrial Commission and which may vary according to local conditions. There is provision for public hearings on the schedules and there may be revisions from time to time. There is also a provision for a Statewide panel, thus giving free choice of a physician by the patient. According to recent estimates the cost of this insurance will be about 24 cents each a week from the employer and employee.

Doctors Vote to Increase Fees.—At a recent meeting of the Medical Society of Bessemer, Ala., the members voted to increase their fees on all calls. Calls during the day were raised from $2 to $2.50 up to ten o'clock in the evening. After this time calls in the city will be $5. Calls to the suburbs will be $3 during the day and $6 at night.

Charitable Gifts.—Fifty thousand dollars, or one-half the amount needed to complete the fund for continuing and enlarging the work of the Social Service Department of the Sloane Hospital for Women, New York City, in memory of Dr. Edwin B. Cragin, has been raised by voluntary subscription.

By the will of the late Dr. James Tyson of Philadelphia conditional bequests are made as follows: Rush Hospital for Consumption and Allied Diseases, $3,000; Publication Fund of the College of Physicians of Philadelphia, $500; Mutual Aid Association of the Philadelphia County Medical Society, $500.

Entertainments given by visitors at Palm Beach recently have netted $2,871 for the Pine Ridge Hospital, which was established in that locality a short time ago.

Civil Service Positions Open.—The New York State Civil Service Commission announces the following vacancies to be filled by competitive examination on April 26: *Director of Laboratory*, Department of Health Office, Port of New York, Rosebank, S. I., N. Y. Applicants for this position, which pays $3,500 a year, must have a broad theoretical and practical knowledge of bacteriology as well as a knowledge of general pathology. Experience and executive ability to conduct a laboratory in a businesslike and methodical manner are also required. *Assistant Physician*, regular or homeopathic. This examination is intended to provide eligibles for the position of assistant physician in the State hospitals and for other institutions of a similar nature in various State and county institutions. The salary is $1,200 a year with increase. The examination is open to both men and women who are licensed to practice medicine in this State. Applications must be in the hands of the Commission at Albany not later than April 16.

Scholarships for Nurses.—The American Red Cross announces a scholarship fund of $100,000 to induce graduate nurses released from the Army and Navy Nurse Corps to train for public health nursing. A maximum scholarship of $600 will be granted for an eight months' course of training and $300 for a four months' course. The fund is to be administered by the Red Cross Department of Nursing, and scholarships will be granted on the recommendation of Red Cross division directors of public health nursing.

Eugenics Memorial Planned.—The Eugenics Research Association of Cold Spring Harbor, L. I., proposes that a "Roosevelt Institute of American Family Life" be organized and developed in connection with the eugenics record office of the Carnegie Institution at Washington. The object of proposal is to provide an institution to combat "race suicide" and to "advance those ideas of responsibility and patriotic parenthood for which Theodore Roosevelt so valiantly battled."

Obituary Notes.—Dr. JOHN HENRY BRADSWORTH, a graduate of the Hahnemann Medical College, Philadelphia, in 1889, died at his home in Patterson, N. Y., on March 21, aged 71 years.

Dr. JOHN G. HERSH died of bronchopneumonia at East Greenville, Pa., on February 23, at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1876. He served in 1899 as Representative in the State Legislature from Montgomery County. He was a member of the Chester County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. WILLIAM HUGHES WELLS died at Philadelphia on February 24 at the age of 59 years. He was graduated from Jefferson Medical College in the class of 1891. He was assistant professor of obstetrics in his alma mater, assistant obstetrician to Jefferson Hospital, pediatrician to the Charity Hospital, and physician to the Willing Day Nursery. He was a Fellow of the College of Physicians of Philadelphia, and a member of the Obstetrical Society of Philadelphia.

Dr. MAX STALLER died at Philadelphia, of carcinoma of the larynx, on March 2, at the age of 51 years. He was graduated from the University of Illinois College of Medicine in the class of 1895. He was one of the founders and first president of Mt. Sinai Hospital and attending surgeon, and medical director of the Jewish Consumptives' Institute. He was a member of the Philadelphia Medical Club, the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. JAMES E. COOPER, a graduate of the College of Physicians and Surgeons, New York, in 1867, died suddenly from apoplexy at his home in Shrewsbury, N. J., March 19, aged 75 years.

Dr. FRANCIS RAND BLANCHARD of Eaton Rapids, Mich., was killed by a fall down an elevator shaft at the Harriet Chapman Hospital, on March 4, aged 55 years. He was a graduate of the University of Michigan, Ann Arbor, in 1891, a member of the Medical Reserve Corps, chairman of the local branch of the American Red Cross, and founder of the Harriett Chapman Hospital.

Dr. GEORGE W. KUNZ of New York died of pneumonia at the Lenox Hill Hospital, on February 13, aged 54 years. He was a graduate of Bellevue Hospital Medical College, in 1887. Dr. Kunz was assistant surgeon to the New York Eye and Ear Infirmary and attending otologist at St. Bartholomew's Clinic.

Dr. JAMES THOMAS MEEHAN, a graduate of New York University Medical College, in 1882, died at his home in New York City, on March 16, aged 59 years.

Correspondence.

ACUTE DILATATION OF THE STOMACH.

To the Editor of the Medical Record:

Sir:—Your editorial on this subject in the issue of March 1 interested me very much. These cases are rare. To my knowledge, I have seen but one. That was at least thirty years ago, when I was called to see what massage might do. A very few minutes of this convinced me of its futility. I turned the patient in the prone position, on his chest and abdomen, not dreaming that I was doing anything wonderful. The brother of the patient, a distinguished surgeon, could not see any sense in such a simple procedure, and objected, so it was abandoned. It might have saved the patient's life, according to your editorial, which gives credit to Schnitzler of Vienna for having first recommended it. Every day I am sure that every physician, surgeon, and layman who has any "gumption" at all uses devices far more ingenious than that without thinking he is making an invention.

Before Schnitzler was ever heard of, your distinguished confrère, Dr. A. J. Gallant of New York, proved massage to be not only safe but highly advantageous, as early as thirty hours after operations upon the abdomen. After the failure of laxatives, enemata, and the use of the rectal tube, he has been able in all the cases he has attempted to relieve the bowels of their painful distention and cramps from gas, and he doubtless in this way has saved life. Massage over the ascending transverse and descending colon was followed by the escape of gas, affording the patient great relief and comfort in the course of 10 or 15 minutes. Changing the patient from the back to the side was also found useful in taking the "kinks" out of the bowels. Infection of the line of union or damage to the structures involved in the operation is not likely to occur from the use of massage thirty hours after the operation. Most of the cases reported were for operation upon the uterus and ovaries and for appendicitis and hernia.

Patients suffering from abdominal truoble are apt to have mental peculiarities which the physician will do well to steer clear of, if he can. It was a wise man who said you can't Christianize the world until you have cured dyspepsia. Conversely, patients suffering from mental illness will often be found to have strange conditions of the abdomen. In two I observed extreme relaxation of the abdominal walls, which had been overlooked by the physicians who asked me to give them massage, to which they responded remarkably well. We hope to hear more about the interrelation between abdominal and mental trouble from those who have ample opportunity to observe.

A few years ago we heard a great deal about the benefits to be derived from persistent exercises in locomotor ataxia, and they were called after the man Frenkel, who was said to have invented them. As well say with Sancho Panza, "God bless the man who invented sleep." He does not even advocate the proper manner in which they should be used, such as I have described in my treatise on massage.

Douglas Graham, M.D.

Boston, Mass.

THE HEALTH INSURANCE HEARING.

To the Editor of the Medical Record:

Sir:—The newspaper accounts of the hearing on "Health Insurance" before the Judiciary Committee of the Senate on Wednesday last overlooked or omitted to mention certain important facts in connection with this event. The event that received no comment was the appearance of the president-elect of the American Medical Association and late president of the Medical Society of the State of New York among those who favored this bill, while the entire medical profession of the State as represented by the council and president of the State Society with representatives from all the county societies appeared in opposition to it. Neither the *Sun* nor the *Times* noted this appearance at all. The *Herald* and the *Tribune* reported it, the latter referring to the president-elect as "chairman of the Social Insurance Company of the American Medical Association."

None of the arguments of the medical men against putting the practice of medicine under the State Federation of Labor which controls the State Industrial Commission were given. Every plea, however specious, of the labor leaders was reported in full, on the other hand. James M. Lynch, State Industrial Commissioner, and James P. Holland, president of the State Federation of Labor, were the most favored in this respect. Mr. Holland repeated his annual threat that "as labor demanded the passage of this bill, its demands sooner or later would have to be met whether the doctors objected to it or not." Mr. Lynch saw the brightest augury for the future of Compulsory Health Insurance in the argument that it was unconstitutional. This, to him, was the most promising and potent feature for its success in the present state of the public mind. Some of the arguments that were not reported against the unionizing of medicine under the bill were that medical men were accustomed to work more than eight hours, that if they were called upon to strike the time chosen would in all probability be during the prevalence of an epidemic, and that, while there was nothing derogatory to labor in "working for its pocket all the time," this practise was against all the established principles of our once honored calling. An editorial from a New York newspaper read by Senator Davenport at the hearing compared Health Insurance as a measure of reform to the Workman's Compensation Law. The Senator was told in reply that when the sick poor were exploited by the medical profession as the injured workmen were by the chartered insurance organizations of the State, as well as by the administration of the law under which they lived, we would be the first to demand a form of "Health Insurance" for their protection.

John P. Davin, M.D.

117 West Seventy-sixth Street.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, February 27, 1919.

Medical Questions in Parliament.—There can be no doubt that medicine is going to come by its own in the new Parliament if the number of questions having a medical bearing which have already been raised can be taken as a guarantee

that a certain proportion of them will be closely discussed. In the last week of February around the Ministry of Health Bill were concentrated some of the most important debates of the House, and members of Parliament, regardless of party, took part in the discussions and showed by their words that they considered the Ministry of Health to provide an unrivalled opportunity for the amelioration of all classes of society. But apart from these important debates a large number of medical questions were raised in the House and received, from the various Ministers in charge of the departments implicated, detailed replies showing that it is the intention of the Government to give as far as possible full play to medical views on domestic government.

The outbreak of rabies in the southwest of England was, for example, fully described by the parliamentary secretary of the Board of Agriculture, whose explanation showed that 94 cases had occurred in Devonshire and 24 in Cornwall but that efficient work by the responsible local authorities had now gone far to stamping out the epidemic. The Board of Agriculture, however, deprecated the view that the danger was over, and a system by which the patients—civilians, soldiers and sailors—should be promptly subjected to Pasteur treatment for hydrophobia will continue. (This has been reported previously in your columns.) On the same day the home secretary answered categorical questions as to the inadequate accommodation for mentally deficient persons throughout the country. To begin with, he admitted the inadequacy, which is, in itself, a sign of progress, for, until recently, no Government Department ever admitted that, from the medical point of view, its provisions were not as perfect as official advice could make them. The defence that action is taken or inaction is condoned under official advice obviously no longer holds good in the House of Commons.

The home secretary on the same day, admitted, in reply to questions, that under stress of war the activities of the local authorities in dealing with mental defectives had been curtailed, but he asserted that the Board of Control, the bureau having charge of this section of local government, was immediately issuing a circular letter to the local authorities on the subject. No doubt there is room for a great deal of hard work here, for the trials of the past four years have led to much mental breakdown, and acute medical discrimination will be required to decide what of this is permanent, what is capable of amelioration, and what are the best therapeutic methods. Almost simultaneously the home secretary was asked whether he was aware that Assistant Medical Officers of Asylums were not allowed to marry, and, if so, whether that rule would be rescinded. The significance of the question is, that the best young men want to marry, and that, if the asylums are to be staffed by such officers, no disability compelling them to remain bachelors ought to be maintained. The treatment of the mentally deficient should largely be in the hands of capable men, and no step should be omitted to secure this. The home secretary admitted the justice of the argument by stating that the Board of Control were already using their influence to secure the provision of such accommodation as would enable the Senior Assistant Medical Officer to marry, and, in larger institutions, the Second Assistant Medical Officer; so that marriage would be their natural course. Undoubtedly until now the question of accommodation has been at the bottom of opposition to this needed reform, and the probability is that separate houses will be provided in the grounds of county asylums enabling the staff to lead the proper domestic life in a wholesome environment which is particularly needed in a very wearing occupation.

The medical treatment of discharged soldiers has also been discussed under a reply of the Parliamentary Secretary to the Secretary of Pensions, and one side of this question, namely, the care of the tuberculous soldier, has also received considerable attention. The debt of the country to the unfit soldier and sailor is one that all classes would wish to have generously discharged, but on the other hand it is reasonable that a Government, sorely burdened with financial responsibilities, should exercise some care in the matter. A soldier is found to be tuberculous: has the infection been incurred while serving as a soldier, or was it latent and called into activity by service as a soldier; or is he the subject of a widespread infection which was as likely, and perhaps even more likely, to attack him in civilian life than while serving his country These are large questions, and large issues depend upon their proper answer, but it is of good omen that in the existing Parliament there should be a readiness to discuss them.

The Ministry of Health Bill.—Various bodies representing activities, groups, and sections of the medical profession are now beginning to take an active interest in the bill, as the intention of the Government to pass it into law with all expediency has become obvious. The General Medical Council has been invited by the Lord President of the Council (that being the cumbersome title of the chairman of His Majesty's Privy Council), to express opinion upon the measure, and this, the General Medical Council has accordingly done through its executive committee. The General Medical Council point out to the Privy Council, while generally blessing the bill for its consolidation of public health powers and duties, that it is extremely important to introduce legislation corresponding to that proposed by the bill for England, Scotland and Wales into Ireland, and the good sense of the suggestion is obvious.

A joint committee of the English Royal Colleges has also issued a memorandum upon the bill which it has had under consideration for some time. The committee presumes that its memorandum deals only with the English and Welsh position, leaving Scotland and Wales to voice their own views; and in the next paragraph is prepared to receive the new government-administration of medicine without enthusiasm, evidently thinking that the measures for the maintenance of health of the community will not receive their best opportunity if administered by any existing bureau too entirely. But it is in the matter of a Medical Advisory Council to assist the minister that the

English colleges take a very firm and useful stand. They say:

"Considering that a large proportion of the work of the Health Ministry, both as regards its policy and its execution, will depend on the knowledge and cooperation of the medical profession, the Joint Committee considered it essential that there should be appointed by the Minister of Health a Medical Advisory Council, drawn from every section of the profession, such council to have direct access to the minister, and the power to initiate advice. Since there will probably be other advisory Council, besides the Medical Advisory Council, the Joint Committee is of the opinion that there should be a connecting committee in the ministry for the correlating of the work of the Advisory Councils in order to prevent overlapping and conflict of advice. The Medical Advisory Council to be of real use to the minister, and through him to the nation, must be of limited size —say, 21 members. It cannot, therefore, be representative of the members of the medical profession in the Parliamentary sense. Its members must be not only individually excellent, but such as will together constitute a good council of advisers."

The composition of the Medical Advisory Council may turn out to be the most important thing in the bill from the professional point of view, and the Royal Colleges have shown discrimination in fastening upon the point that the constituent members must be a good team as well as good individuals. Too often combinations of all the talents have proved sterile, producing by their stock of brilliant antagonisms nothing but sterile commonplaces.

A Medical Advisory Council, by the way the official style of the body will probably be "A Medical Consultative Council"—should include primarily original workers along special lines, so their voices of authority may be heard and the risk of compromise annulled. The Royal Society of Medicine and the British Medical Association are in like manner watching and reporting upon the Ministry of Health Bill, with the result that these bodies are in sympathy with the views of the Royal Corporations. Dr. Addison, who has charge of the bill, will therefore be placed in good time in possession of ideal authoritative medical views.

The Troubles of British Dental Practice.—A report has been received this week from the Privy Council Committee appointed to inquire into the extent and gravity of the evils of dental practice by persons not qualified under the Dentists Acts. The terms of reference of the committee were generally to investigate in accordance with the purpose of their appointment, but specially to consider and report upon three things:—(1) the cause of the persistently inadequate supply of qualified dentists and dental surgeons: (2) the expediency of legislation prohibiting the practice of dentistry and dental surgery by unqualified persons; and (3) the practicability, without impairing the existing guarantee for efficient practice, of modifying the courses of study and the examinations prescribed for dental qualification, by reducing the time occupied and diminishing the cost of training. The Rt. Hon. F. D. Acland, M.P., acted as chairman of the committee, which included Lord Knutsford, chairman of the London Hospital, Sir Almeric Fitzroy, secretary to the Privy Council, Mr. C. S. Tomes and Mr. W. H. Dolamore, well-known dentists, and the principal medical officers of the local Government Board and of the Board of Education. It will be observed that in the terms of reference it was definitely assumed that the supply of qualified dentists and dental surgeons in the country was inadequate, and it is difficult to contest the point. None the less it is denied and on this ground. Every qualified medical practitioner is *ipso facto* a qualified dentist, and could if he chose practise that branch of his profession exactly as he can practise ophthalmology or any specialty. The reasons why he does not do so are, first, that his fees in any dental practice except high-class practice are not inviting; and second that a special diploma exists, qualifying in dentistry alone, and those who possess diplomas of larger range do not compete in any number with the special men. The possibility of forbidding dental quackery by law compelled the committee to face the difficult situation of suspending from their avocation a large mass of perfectly respectable and competent people who are at the present moment practising dentistry without a qualification. Of course such a roll includes a number of mischievous and even dangerous persons, but this is not to say that the unqualified dentist is necessarily either a quack or ignorant of his business. It will be seen therefore that the task which lay before the departmental committee was by no means an easy one.

The institution of the inquiry has been quickly justified by the commission, who point out in drastic manner in the third and fourth sections of the report that the risk incurred by the public is very real under existing British law, where any person, however ignorant, unskilled or untrained, can practise dentistry with freedom, and can inform the public by advertisement or otherwise that he is so practising. The only protection the public has in such circumstances is an action for damages where injury has ensued, and the only deterrent on the part of the unqualified dentist is his fear of a possible prosecution for manslaughter in case of death. Unless a coroner inquires into some glaring example of malpractice, the dentist quack may perpetrate his "dental" enormities with impunity. Severe injuries to the mouth and jaws, septic poisoning and deaths from the unskilful administration of anesthetics are among the tragedies which have followed unqualified dental practice in this country, and there can be little doubt that the recommendation of the Commission that the law should be altered "so as to secure the prohibition of the practice of dentistry by persons not registered" will be acted upon. With regard to the shortage of registered dentists the departmental committee has agreed that it exists. There are only about 5,000 names upon the dental register and assuming that these probably qualified men, and these only, are likely to practise dentistry the shortage may be considered proved. With a view to providing for this shortage all the obvious means are proposed to

be taken. The time, it is suggested, must be reduced during which the student is to be trained, and scholarships for dentist students and dental mechanics must be founded. To relieve somewhat the cost to the individual patient the establishment of a public dental service is put forward as a means of placing the payment of a large number of dentists upon the public expense. Lastly, and this recommendation of the Commission may have been made with hesitation, the commission is willing to admit to a new register a certain number of properly vouched-for unqualified practitioners.

The Influenza Epidemic and Its Prevention.—As in many other parts of the world, so in the United Kingdom the recrudescence of influenza of a serious type has much embarrassed public affairs, and has exacted from the population a serious toll of life. We are still on the rising wave of a third pandemic, and the age incidence of the third outbreak continues to show a marked virulence toward the elders, which was specially absent in the previous attacks. The Local Government Board has issued a memorandum full of pious advice—cultivate good habits; lie up early when attacked; avoid infection where possible; and so on—but the memorandum gives little definite advice beyond prescribing a gargle. This is not the fault of those who have issued it, for in the absence of any certain information about the germ of influenza direct or specific therapy must be all guesswork. Many of the public would have welcomed a government order enjoining the use of masks, but masks permitting of respiration and vision would probably be permeable by any spittle borne germs. Many medical men are sure that vaccines have been useful, but there are at least as many records of failure as of success. But so much and such widespread attention is now directed to possible immunization that the hope of some definite and early information is reasonable.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, February 1, 1919.

The Army Leave Area at Nice.—The Army Headquarters has created two great leave areas; one in Savoie in the north of France with Aix-les-Bains as its center and another on the Mediterranean with Nice as the center.

Nice is the greatest American Resort in Europe. More Americans gather here during the season than in any other European pleasure center. In 1890 Nice was a place of 60,000. It now has 175,000. No city in France has had such a percentage of increase during the past century, and this unprecedented growth can be attributed almost wholly to the American patronage.

As a first step, the army authorities secured four of the large modern hotels as hospitals for long term and convalescent patients; the Y. M. C. A. immediately came along and took over the Jetée Promenade, a handsome, imposing building built over the sea, comprising a concert hall, theater, and enormous reception rooms; here the "Y" has its headquarters. A military band gives daily concerts in the great reception hall where three thousand can circulate. In another large hall an orchestra plays afternoon and evening for dancing. In the concert hall there are daily entertainments by the traveling vaudeville and special artists employed by the amusement department; afternoon tea is served with cakes and biscuits, at a minimum cost. An excursion bureau books those who want to take in the diverse excursions to Mentone, Monte Carlo, Cannes, Grasse, and the Litorale. An information bureau helps newcomers to locate rooms and boarding places and gives information as to the fixed rates of various hotels. In the center of the great hall a canteen is placed where all the ordinary wants of the men can be supplied at cost, as at the commissary.

For the officers, the building of one of the city clubs, on the Place Masséna was requisitioned, comprising reading, writing, smoking, billiard, card, and lounging rooms and a large hall where an orchestra plays afternoon and evening for dancing, and here I find exercised for the first time a comprehensive and concerted plan for controlling the habituées of a place of amusement created for the benefit of the army. No lady is admitted to this club without a card of admission, no matter if she be accompanied by an officer.

Applications for cards are made by the ladies themselves or by their friends, giving name and residence and the names of two city references. These cards are handed over to a French committee named the committee of French Homes, who investigate the references and accept or reject the application. This has resulted in bringing together for the afternoon and evening dances the mothers and daughters of the best families and the exclusion of all questionable characters. The cards are issued for a given period, which permits the retiring of any who by any means have secured cards and are found questionable. Here also is a supply depot of cigars, tobacco, cigarettes, candies, eatables, and little necessaries very convenient to those constantly coming and going.

The dancing hall has been found too small to accommodate the crowd that daily frequent it and arrangements are being made to double the floor space. So far, there are not enough ladies to pair with officers, who outnumber them 3 to 1, but new cards are constantly being issued and this promises to become the most popular resort in Nice.

A very pretty and commodious theater has been taken over and consecrated to the nightly entertainment of the officers, free of charge of course, and here there flows the regular stream of Y. M. C. A. corps of entertainers, numbering thousands.

The Red Cross have a commodious club for officers on the Promenade des Anglais, comprising reading, lounging, and tea rooms, where tea and cakes and American home-made pies are served daily free to all in uniform. This one club does not seem to be popular or largely frequented despite the fact that it is the only resort where refreshments are furnished free, and I think the chief reason is that ladies are not admitted. If the officers were permitted to bring their lady friends, paying for their entertainment, I am of opinion this club would daily be crowded, for it looks out over the sea, is commodious and luxur-

iously furnished; but afternoon tea is a distinctly social function and a man does not care to go in and sit alone, no matter what the advantages.

The British Y. M. C. A. have rooms on the Promenade where they serve real ice cream three times per week, and this long unknown luxury brings together a crowd on ice cream days. Also the Knights of Columbus have club rooms pleasantly situated and much frequented.

There is a beautiful golf course just out of the city bordering on the sea, which with the snow-capped mountains for a background forms a paradise of beauty these sunshiny days. Nice has two fine public tennis courts open to officers at one-half rates and there is good fishing off any part of the coast, so that from morning to midnight men on leave can find healthy occupation and amusement in the midst of the finest paradise this world can offer.

The transportation authorities have decided to run a special Riviera express for all officers and men proceeding south on leave. The new service will be known as the "A.E.F. Personnel Special Train Service," and will run between Paris and Mentone daily, on and after February 17 next. The train will be reserved exclusively for A. E. F. Personnel, which is understood to include American Red Cross, Y. M. C. A., Knights of Columbus, Salvation Army nurses, naval attachés, as well as officers and enlisted men of the army proper.

8. Envenomization Suggested as Etiology of Hydrophobia, Yellow Fever, Rocky Mountain Spotted Fever, and Cowpox.—Anne Young has noted a striking parallelism between the symptoms and pathology produced by bites of venomous animals and hydrophobia and suggests that the failure to demonstrate bacteria or protozoa in hydrophobia may be due to the fact that they are not the causative factors. She points out that a dog manifesting rabies is not necessarily suffering as a result of a bite from a rabid animal, but may have eaten an animal dying or dead from the bite of a venomous animal and that the fact has not been sufficiently recognized that the muzzling of dogs prevents them not only from biting, but also from nosing and coming in contact with or eating the flesh of animals that have been bitten by a viper. Human beings have been poisoned by eating the flesh of cattle poisoned by eating blister beetles. It is possible that infantile paralysis and beriberi may be caused by a neurotoxin venom. Yellow fever, cowpox, and Rocky Mountain spotted fever are possible results of a hemolytic venom, and in the case of yellow fever a sick stegomyia may inoculate a venomous digestive substance, which is a feasible explanation of infected eggs. In the preparation of the Pasteur treatment for rabies the virus is fixed by passage through successive rabbits; may not the same procedure take place outside the laboratory, but not necessarily through the same host? She suggests that in the investigation of obscure diseases, envenomization is at least worthy of elimination.

3. The Reliability of the Nystagmus Test.—Lewis Fisher and Harold L. Babcock refute the contention that there is a suppression of the eye reaction in persons subjected to certain types of acrobatic exercises. They point out that since clinical medicine has relied for years on the permanency and constancy of reflex phenomena, the question of the reliability of reflex response is a most important one and, therefore, it was natural that the theory, promulgated by certain psychologists, that persons subjected to considerable whirling or tumbling lost their nystagmus as a result of their training, should be made a subject of investigation. Attention was first directed to the nystagmus reaction in aviators, since flying, and especially stunt flying, entails a great deal of whirling. It was found that fliers of even 2,000 hours' experience exhibited a good active nystagmus of approximately 24 seconds, and whenever possible these findings were checked up with the nystagmus findings of the same persons at the time of their original examination; in no instance was there found a reduction in the duration of the nystagmus. At Mineola 942 veteran fliers were examined and similar investigations were conducted by trained otologists in other flying fields throughout the country, with identical results. A large number of acrobats and whirling stage dancers were also examined, the average nystagmus in these persons being 26.1 seconds on turning to the right, and 26.05 seconds on turning to the left. A series of experiments was also undertaken by the Otological Department of the Medical Research Laboratory at Mineola, in which persons were subjected to frequent rotation in the turning chair to determine whether the results obtained were in accordance with those reported by a group of psychologists who carried out a similar series of experiments and who found that persons who started with a nystagmus of 24 seconds or more, on being subjected to daily turnings for several weeks, would show a complete loss of nystagmus reaction to turning, or a marked diminution. The results of the Mineola experiments, however, clearly indicated that (a) not a single subject lost the nystagmus; (b) not a single subject showed even a marked impairment of the nystagmus reaction. Fisher and Babcock conclude, therefore, that (1) The duration of after-turning nystagmus is not impaired by flying. Such a very large number of aviators have been reexamined as to make this conclusion absolute and final. (2) From the evidence at hand, it would seem that in acrobats, whirling dancers, airdrome performers, and in athletes in general, there is no diminution of nystagmus response. More examinations of such persons, however, would be necessary before any final conclusion should be drawn. (3) Repeated turning experiments on normal persons occasionally produce an "apparent" and slight shortening of the nystagmus, but that this is only apparent and not real is demonstrated by the convex glasses. (4) In medical practice, an absence or impairment of eye responses following ear stimulation definitely indicates a pathological condition within the vestibular mechanism.

2. The Buried Sequestrum: A Post-war Problem.—Major James Phillips draws attention to the fact that surgical skill will be required for a long time to come to remedy conditions resulting from gunshot wounds received during the war. The cases reported in the present article have been treated in the Bradford War Hospital in England, where the method indicated by the author has been followed since 1917. The buried sequestrum is associated with the extraordinary multiplicity of comminution which characterizes war wound fractures. The bone is splintered into many fragments; the periosteum is torn and separated from the bone; the spaces between the various fragments and between them and the periosteum become filled with new bone, in the midst of which lie one or more sequestra, which are responsible for the persistent suppuration. In the majority of cases *x*-ray examination is of little aid in diagnosis, nor does the condition or direction of the sinuses throw much light upon the character, size, or position of the sequestra. The only treatment likely to be successful consists in baring the bone from overlying soft tissues and freely chiseling through bone until the sequestrum is exposed. This is a severe operation and, as multiple sequestra are not uncommon, more than one operation may be required. The removal of necrotic tissue makes it possible to treat bone cases by the Carrel method; the wound can be made surgically clean and secondary suture successfully practised. Illustrations are given showing the manner in which overgrowth of bone takes place. In all cases in which rough, bare bone, felt by a probe or a persistent sinus, leads to the seat of an old bone injury of the femur, and especially if the *x*-ray examination points to sequestrum formation, the author operates in the following way: An incision long enough to permit of the exposure of the whole of the damaged area of bone is made and carried down to and through the periosteum. All the soft parts, including periosteum, are cleared from the bone with an elevator; bony irregularities are chiseled away, sinuses in the bone are followed up, and an attempt made to find and remove all sequestra—an operation which may present no little difficulty. In the case of a patient who has been absorbing toxins from a suppurating wound possibly for months, the necessary chiseling may be associated with a good deal of shock; the author, therefore, on more than one occasion, has thought it best to complete this stage of the operation at a later sitting. When every obvious crevice and cranny in the bone has been smoothed away with the chisel, the soft parts are stitched *open* by passing one or more mattress sutures of thick iodined silk through the muscles and then through the skin at some distance from the edge of the wound. The wound is sterilized by Carrel's method. Dakin's solution is instilled every two hours and at least once in 24 hours a thorough cleansing of the wound is undertaken. When the cavity is deep it is important that the gauze and wool swabs used for packing be counted. At first the packing is likely to cause pain and may have to be done under an anesthetic; sepsis is the chief cause of pain, however, and as the wound becomes sterile the pain and tenderness disappear. The discharge is examined bacteriologically twice a week, and when the "film chart" shows three or less organisms per field the wound is closed. In this operation the granulations are thoroughly curetted, the soft parts are raised from the bone until they can be brought together without tension, and the skin is freely undercut and its edges trimmed. The undercutting is essential if a non-adherent linear scar is to result. The raw surface is swabbed first with methylated spirit and then with bipp. A running catgut stitch brings the deep fascia edges together over the muscles. Thick silk stitches are passed through all the soft tissues so as to close the wound, leaving no dead cavity. A continuous catgut stitch is used to secure accurate apposition of the skin edges. An absorbent dressing is applied and left in position for fourteen days; it is then renewed, but the sutures are left *in situ* for another week. In making free incisions care, of course, must be taken to avoid the nerves. When the fractured bone is subcutaneous or poorly covered with soft tissues, different treatment is required. Phillips reports the case of a man admitted to hospital with badly smashed tibia and fibula. Carrel's tubes were inserted and the leg was placed in Thomas' splint. Firm union of the fibula and partial union of the tibia took place and the extension apparatus was removed. A month later, the clean, granulating surface over the front of the head of the tibia was skin grafted. No dressing was applied, the leg being simply covered by a cage. Two weeks later, the graft wound had healed and the patient was getting about on crutches. In this case the bone continued to form beneath the healed grafts, a phenomenon which had been noted in other cases. Phillips adds that in such cases the radical methods described are the only ones likely to lead to healing of what must otherwise remain, in many instances, permanently discharging wounds.

3. Note on the Use of Ionization in the Treatment of Certain Types of Facial Scars. Lieutenant H. S. Carter and Captain A. D. E. Shefford.

3. Note on the Use of Ionization in the Treatment of Certain Types of Facial Scars.—Lieutenant H. S. Carter and Captain A. D. E. Shefford submit the results they have obtained by ionic treatment of facial cicatrices, due to war injuries of the facial tissues, and especially where damage has been done to the masticatory muscles, a method of treatment which has received scant attention. They point out that the commonest disability arising from such injury is the condition of "false" trismus, which is due, as a rule, to one of three causes: (1) Fracture of the ascending ramus of the mandible, with actual damage to contiguous tissues; (2) In the absence of fracture, injuries of such a nature as to involve some fibers of the masseter, temporal, or pterygoid muscles, the scar tissue limiting movement; (3) Reflex spasm of all the masticatory muscles consequent upon organic injury of remoter parts. These observers have found that the treatment of scars by ionization results in a progressive decrease in their densities and an increased flexibility, both subjective and objective, with marked permanent improvement in ability to open the mouth and masticate. This has definitely occurred even when ionization has been unaccompanied by intraoral gagging or facial massage. Cases in which there is adherence of scar to osseous tissue often require treatment for three months or more. They have used the alternating current from the city mains, which is run through a motor transformer so as to give a constant current of 100 volts E.M.F. This is conveyed to the patient through a distributing board, fitted with a wire resistance rheostat for the purpose of varying the strength of the current, and with a milliammeter for registering the amount of current used. The electrodes consist of small zinc plates about two inches square, between which and the skin they place from sixteen to twenty-four layers of folded lint. These coverings are about half an inch larger all round than the metallic electrodes, in order to prevent possible burns by contact of the metal with the skin. The pad of the negative or active electrode is soaked in the therapeutic agent (in Carter and Shefford's cases NaCl, KI, or sodium salicylate) in 1 or 2 per cent. solution in hot distilled water. The pad of the positive pole is soaked in hot water to which a trace of sodium chloride has been added to ensure easy passage of the current. The negative electrode is placed over the cicatricial area, while the positive electrode is placed under the chin (most often) or over the deltoid or on the nape of the neck. These are made secure by bandages which also ensure efficient contact with the skin area to be treated. The current is turned on very slowly, and they start with a current of 2 to 3 milliampères, gradually working up, according to the patient's tolerance, to 15 or 20 milliampères. The

maximum current which each patient can support comfortably varies, and is usually not reached until the third or fourth treatment. By this gradual method these observers have been able to obviate the unpleasant after-effects of headaches, vertigo, and nystagmus, which are liable to occur from the passage of an electric current so near to the semicircular canals and their endolymph system. The duration of each treatment was from thirty to fifty minutes, daily when the condition of the skin permitted, and on alternate days when the skin was sensitive. They point out that it is useless to attempt ionization when oral sepsis is present, or, at any rate, until it is under control; also that it should not be used while metallic foreign bodies exist in the tissues, otherwise burns are liable to occur, with the formation of slowly healing ulcers. In the event of an abraded surface happening to be in the area under treatment, it is sealed with a drop of collodion, which is allowed to dry before proceeding. If a small indolent sinus persists, it is plugged with gauze soaked in the electrolyte used and usually heals early in the treatment. At the end of each treatment the current is always gradually reduced before withdrawal to avoid unpleasant subjective shock to the patient. It should be remembered that the ionic effect is directly proportional to the intensity of the current and the time of application, so that as large a current as can be comfortably borne should be used, and the treatment should be of a long rather than short duration.

In the experience of the authors, sodium chloride as an electrolyte has given the best results. Ionization with iodides or with sodium salicylate is useful for the alleviation of pain, but with iodides is apt to cause irritation of the skin, and as far as softening of the scar is concerned, the sodium chloride is more effective than either of the other drugs. It was found that better results were obtained with the negative pole as the active electrode, but there seems to be no doubt that this was due to a considerable extent to the condition of induced hyperemia, which persists for an hour or two after treatment. The authors consider it improbable that the ions penetrating the tissues, or formed in the tissues by the passage of the current, retain their ionic or active state for more than a fraction of time, but believe that they immediately enter the general circulation in combination as inert substances and that any benefit due to introduction of ions or ionic dissociation in the tissues must be limited to the time of passage of the current and to the period of active bombardment during the actual treatment. The results obtained in 24 cases treated have led the authors to conclude that the method indicated may with advantage, be combined with the mechanical procedures of intermittent intraoral gagging and massage, the best results being given when the gag is applied for an hour immediately before treatment (in cold weather the area to be treated should first be thoroughly warmed with hot water or by radiant heat), and that in the treatment of facial cicatrices ionization is of undoubted value. The circulation through the scar tends to become reestablished; there is loss of stiffness and adherence, permitting the play of underlying muscles and reduction of the limiting effect of the scar upon the masticatory muscles; and in cases where the edges of the flaps, after facial plastic operations, are rolled and thickened, causing retraction of surrounding normal tissues, softness and flexibility are increased and the deformative effects of such scars are diminished.

Berliner klinische Wochenschrift.

January 20, 1919.

Abdominal Drainage After Laparotomy.—W. Nagel is in favor of drainage after abdominal operations and says that it is too much neglected at present. Drainage prevents the formation of blood or serous collections which offer an excellent culture medium for later infections. Drainage may be made through the abdominal incision or vagina. The reality of an ascending infection from the vagina is a myth. The writer advises drainage with the cigarette drain, such as he has seen employed by American surgeons.

Blood Pressure in Healthy Men.—F. Groedel refers to the divergence of opinion existing in the profession in regard to blood pressure, as well as to the various results obtained by different procedures. He publishes the results obtained in healthy soldiers and in children of various ages. The writer's figures are arranged in tables based upon the age, height, weight, chest measure, rapidity of the pulse and orthodiagraphic diameters of the heart. Both the systolic and diastolic pressures increase quite regularly with advancing years, but this is more evident in the systolic pressure and it therefore results that the amplitude of the oscillations of the pressure increases with age (35 mm. Hg. at ten years of age, 60 mm. at sixty years of age). It would also appear from the writer's tables that the height, weight, and the dimensions of the heart increase quite parallel with the pressure. The mean figures obtained in one hundred recruits of twenty years of age were: Height 175.5 centimeters, chest measure 86 to 94 centimeters, weight 69.8 kilograms, pulse 69, maximum pressure 150 mm. Hg., minimum pressure 98.5 mm. Hg., amplitude 60 mm. Hg.

A Case of Quadrilocular Intraabdominal Hydrocele.—Hübotter describes a case of hydrocele of the cord with four distinct pockets having no communication between them. The tumor was supposed to be a hernia and came out of the abdomen, but was easily reduced. After a review of the literature the writer concludes that this case is of extreme infrequency.

Münchener medizinische Wochenschrift.

January 17, 1919.

The Pathogenesis of Arteriosclerosis.—B. Fischer gives a very good exposé of the present state of our knowledge of this subject, which is now fairly well understood. The arteriosclerotic process is essentially a hyperplastic proliferation of the intima and a degeneration of the musculo-elastic layer. The lipoid or calcarious nature of the incrustations on the vessel walls is by no means different in the arteriosclerotic processes. These deposits result from a primary degeneration and may vary in degree, according to the arterial soil. Thus the arteries of the elastic type undergo calcification more readily. Those of the musculo-elastic type are more prone to develop atheroma. As to the pathogenesis, experimental work has shown that injections and divers intoxications play the principal part. Certain diets have produced marked arteriosclerosis in animals. The writer next refers to the relationship existing between arteriosclerosis and functional superactivity of the arteries. The onset of arteriosclerosis can be traced back to infancy and has been anatomically demonstrated in babies. The arteries simply undergo the process of wearing out from advancing age and lose their extensibility and elasticity in a rather constant progression. The inherent peculiarities of each organism favor either a slow or rapid process of degeneration. The presence of cholesterin in excessive amounts is a particularly important factor in the etiology of arteriosclerosis.

Red Light in Therapeutics.—Thedering opposes the exciting inflammatory action of the violet rays to the sedative action of red rays. The cutaneous pigments arrest the ultra-violet rays and at the same time fix the red caloric rays, thus neutralizing the action of the former. Taking these data as a basis the writer has employed red light in the treatment of the following conditions: (1) Inflammation of the skin, following exposure to the sun or to excessive doses of the rays of the quartz lamp; (2) In erysipelas and acute and chronic eczema; (3) In pustular eruptions and (4) In pigmentary anomalies such as vitiligo, ephelides, etc.

The New Problems of Malaria Arising from the War.—M. Mayer sums up the present status of malaria derived from experience acquired during the war. Most of the papers referred to by the writer have been abstracted in the RECORD. The writer states that the mean time of incubation is from ten to twelve days, but may be occasionally much longer, as much even as eighteen months. The question of hibernation of the plasmodium in the interior of the mosquito is regarded as improbable.

The Diagnostic Signification of Urobilinogen in the Differentiation of Cancer and Anemia.—H. Scholz remarks that certain writers have wished to give a certain diagnostic importance to the amount of urobilinogen eliminated in the feces. These should be an index to a more or less intense process hemolysis taking place in the organism (Salomon and Charnass). Pernicious anemia is likewise to be recognized by a marked elimination of urobilin following the destruction of large numbers of erythrocytes; cancerous processes and gastric cancer in partlcular should offer a decrease in these substances resulting from a profound disturbance of the metabolism of the red blood corpuscles. To these remarks the writer offers the following considerations: The hemolytic origin of the pernicious anemias is as yet far from being proved, and experimental work hardly confirms the value of the quantitative analysis of urobilinogene in the feces (examination of thirteen cases of gastric cancer and two of anemia). It was also impossible for the writer to establish a relationship between the urobilin in the urine and the presence of metastatic cancerous foci in the liver.

The Cardiodystrophies and Their Treatment by Intravenous Injections of Glucose.—T. Büdinger believes that certain states of cardiac failure are the result of insufficient nourishment of the myocardium. The failure occurs more easily when the percentage of glycemia falls, the glucose being the essential element of the cardiac function. The writer discusses the indications and technique of glucose injections destined to counteract these states of cardiac asthenia which are revealed on auscultation by weak cardiac sounds over the base of the heart.

The State of Nutrition of the Viennese Children.—Von Pirquet notes the fearful condition of denutrition of the Vienna children. Compared with Camerer's tables of mean normal weight, the children at present are lacking 21 per cent. This state of defective nutrition involves 9.2 per cent. of children.

Influenza.—I. Pal gives a résumé of his experience with influenza. The paper confirms, in a general way, the current views held by the profession in respect to this epidemic affection. The writer offers some remarks on the probable mechanism of death from this disease, which he regards as a "vascular death," resulting from a faulty distribution of the blood, due to toxins acting electively on the peripheral vessels. However, cardiac and vascular medication (digitalis, adrenalin, extract of the hypophysis), is insufficient.

6. Syphilis of the Cranial Bones.—Silvero states that lesions may be of acquired or congenital origin. The hereditary forms may vary from the most simple periostitis to the most grave necrosis and exostosis. There is a special inclination for late hereditary syphilis to affect the cranial bones, especially the frontal bone. In the variety due to acquired syphilis, the lesions are usually a manifestation of tertiary symptoms, and are not very frequent. In his three cases two were benign, and the frontal and parietal bones were affected. In the third case, the temporal bone was also affected and the patient died comatose after having serious meningeal symptoms.

3. The Diagnosis and Treatment of Syphilis. H. C. Donald.

2. The Diagnosis and Treatment of Syphilis.—George E. Pugin Meldon, after briefly sketching the history of syphilis, points out that in looking for the *Spirocheta pallida* two facts are well worth bearing in mind. Firstly, it is the exudate from the base and margins of the sore that is rich in spirochetæ, which can seldom be found in the débris on the surface. Secondly, if the sore has been treated recently with antiseptics, especially mercurial preparations, the search is useless. While it has been shown that the complement fixation can no longer be looked upon as a specific antigen antibody reaction and deducted from the theoretical value, still experience has demonstrated that the Wassermann reaction is a reliable clinical test for syphilis. As far as Meldon's experience goes, a fully positive report by a competent serologist means that, excluding such a condition as yaws, the patient is, or has been, suffering from syphilis. A partially positive Wassermann reaction in a patient who has no obvious wasting disease, points strongly to syphilis, but Meldon thinks it is wiser to have a second test made after a provocative injection of salvarsan before making a definite diagnosis. So far as syphilitic disease of the central nervous system is concerned, a positive Wassermann reaction in the cerebrospinal fluid is practically conclusive evidence of syphilitic disease of the nervous system, the only exception being in the case of a patient with a positive reaction in his serum who is suffering from a nonsyphilitic meningitis. A negative Wassermann reaction indicates that the nervous system is not involved, with the following exceptions: (1) In very early acute meningitis, during the secondary stages, the fluid may be examined before it has had time to become positive. (2) The fluid may become negative owing to treatment, but on account of the disease not being fully eradicated, relapse is possible. (3) In some cases of purely cerebral lesions the fluid drawn off by lumbar puncture may be negative. Meldon thinks that all workers in the genitourinary branch of the profession will agree that we are in a position to promise a definite cure in a comparatively short time to patients who present themselves for treatment while yet in the primary or early secondary stage of syphilis. In the later stages of the disease one does not yet feel justified in making such a definite prognosis. The method which Meldon adopts is to give a course of some six or eight injections of salvarsan, or neosalvarsan, combined with mercurial treatment extending over a period of some twelve weeks. In early syphilis this may suffice, but in later cases more treatment may be required. There is just one point in the treatment of primary syphilis that deserves special mention. This is the local energetic treatment of the chancre. For it is here that there is most danger of some spirochetes escaping and giving rise to a recurrence. In syphilis of the central nervous system if treatment is started early, before there has been actual destruction of nerve cells, and while the disease is still confined to the vascular and intercellular tissues, Meldon believes one may hope for as good results as are got in the later syphilitic lesions of other parts of the body. In nervous syphilis experience has taught us that intravenous injections of salvarsan and neosalvarsan are just as effective as intrathecal injections of salvarsanized serum.

Pathological Anatomy of Influenza.—Two articles appear on this subject from the Berne and Basle clinics. Professor Wegelin of the former has found no autopsy case which did not present some evidence of pneumonia. In the most recent cases the lesion was focal in type, with tendency to hemorrhage, while the entire lungs were hyperemic. These foci are not infarcts, although greatly resembling them. But so numerous and varied are the pathological alterations, and so difficult is it to

sum them up in a few words that a detailed description is only wearisome. Some of the pathological processes seem to be conservative as well as destructive. In some cases the exclusive or predominant work of the hemolytic streptococcus can be traced. It is of interest to note that one year before the epidemic the *Streptococcus pleomorphus* was causing considerable mortality under various forms. This is now identified with the streptococcus of influenza. As often stated elsewhere influenza may kill both by pneumonia and by sepsis. In sepsis from the streptococcus there is in influenza, as in other conditions, a heavy production of toxins which damage severely the viscera and muscles. In many septic cases the lungs are almost normal, which explains certain deaths with minimal lung symptoms. This sepsis is believed to be one of the leading factors in the fatally prognostic cyanosis, the toxin acting somewhat after the fashion of illuminating gas. There is some unknown predisposition which acts in spite of youth and vigor, but none of the factors thus far adduced, as underfeeding, can be held responsible. Occasional factors are active and latent tuberculosis and cardiac valvular lesions. In the second paper by Glaus and Fritsche, assistants of Professor Hedinger, is found a record of over 400 autopsies, with special reference to histological studies. The pneumonia is lobular to pseudolobar and the extreme frequency of hemorrhages must be regarded as a typical find. In the case of a death in twelve hours in a healthy woman of twenty-five the sole find was multiple lobular hemorrhages. The alveoli elsewhere were in part edematous. Whether the occlusion of alveoli by blood and edematous fluid was sufficient to kill by asphyxia is not stated. In general there was a marked parallelism between macro- and microscopic lesions with impossibility of summing up in a few words. The totality of the pathological changes showed marked similarity in the fatal cases, a phenomenon not beheld in other specific diseases where there may be remarkable inconstancies.

Annales de Dermatologie et de Syphiligraphie.

Vincent's Angina Simulating Chancre of the Tonsil Cured by Novarsenobenzol.—Clement briefly describes the case of a soldier who was originally under treatment for some joint trouble when he presented a membranous angina on one tonsil. When reinterned this lesion had undergone change to an ulcer and there was regional adenopathy. The diagnosis was made of syphilitic chancre of the right tonsil and the patient transferred to the venereal section. No secondary manifestations had appeared and the microscope showed Vincent's fusiform bacillus. Patient now underwent further transfer and was isolated, as having a contagious disease. In his new quarters he was given an injection of novarsenobenzol, with almost immediate improvement. After a second injection he made a complete recovery and was pronounced free from the presence of pathogenic organisms. Clinically it would have been impossible to make a differential diagnosis for the lesion characteristic of a certain type of tonsillar chancre was present.

Acanthosis Nigricans in the Cancerous.—Dubreuilh reports a case of this association which has been known to exist for many years. The youth of the patient was remarkable, for he was only twenty-two. He had been interned for a wound when it was noted that he presented a peculiar melanosis. At the same time there were severe gastric symptoms. He improved sufficiently to return to the ranks, but in three weeks was back in the hospital, where it was noted that his melanosis was much worse and was now of a papular character. There were two components, localized melanosis and a more generalized papillomatous appearance of the skin. In other words, he presented the condition acanthosis nigricans. It also became possible to recognize the presence of a probable cancer of the stomach. The hyperkeratosis of the skin became universal and of the highest degree. The author for this particular type would use the designation "melanic papillomatosis of the cancerous" to distinguish it from other forms of acanthosis nigricans. Autopsy in this case showed that the skin was actually the seat of a potential generalized carcinosis, so that we are not dealing with an obscure disease association but a vagary of cancer. The melanosis is doubtless explained by a deposit of cancer material in the adrenals.

A Dramatic Case of Influenza.—Dr. Gonzales Castro of Barcelona describes a case of influenza in his own daughter, who was healthy, twenty-six years old, married, the mother of healthy children, and six months pregnant. On September 20, when a grippe wave was at its height in Barcelona, she was attacked with relatively mild symptoms. On the fourth day there was an exacerbation which for the first time caused the patient to take permanently to bed. The father, apparently himself a victim, was summoned at night to the home of the daughter, whom he found suffering with orthopnea and cyanosis. There was only a dry cough, without expectoration. Both lungs appeared involved in a process which affected much of the bronchial tree and alveoli. Free use of wet cups failed to relieve the orthopnea and asphyxia seemed imminent, while the pulse rapidly became worse. The author seized a lancet and opened a vein in the arm, which gave vent to 300 grams of black blood, and the evil symptoms at once showed decided improvement. To further disburden the lungs the author injected emetin, for the dry cough seemed to indicate the existence of complete bronchoplegia. In forty minutes a profuse, frothy sputum appeared, rosy but not at all rusty or pneumonic. Strong counterirritation followed, for relief was only temporary—dry cups, sinapisms, etc., with oxygen inhalations, all to little purpose—and on the following day a second venesection was practised. The symptoms became aggravated and the cough again became dry, orthopnea returned, and for the first time profound delirium appeared and asphyxia again became imminent. Despite his decision to bleed no more, the author had to do something, and once more the lancet was used, this time with marked benefit. During the next days venesections to the total of six were performed. On the eighth day there was violent coughing and sputum suggesting a fibrinous cast of the bronchial tree was expelled. For a while the lungs were unburdened, but the picture returned and the respirations became sixty a minute. The patient was given up and the mother begged the author to give a narcotic to render death less agonizing. He gave an injection of heroin and the next moment was unforgetable. The entire picture changed strikingly for the better. Strangulation ceased, consciousness returned, and the patient fell into a natural sleep for many hours, to be awakened by a return of the distressing symptoms. Fleshy masses of fibrin were again expelled, after which patient again improved. Heroin injections were repeated whenever dyspnea appeared. Improvement was progressive and on the eleventh day the patient was afebrile. But a relapse set in, in the shape of alarming cardiac symptoms. The author for the first time mentions counsel (which he probably had throughout the illness). He now feels that the account of his case is so marvelous that testimony of others should be cited. One of these, Dr. Crespo, testifies that he saw the patient on October 7, the eighteenth day of the affection. The condition was recognized as heart flutter, doubtless the result of toxemia and due perhaps to the toxins formed by Pfeiffer's bacillus, which has been credited with this form of pathogenicity. Digalen given by mouth and intravenously gave a brilliant result. Caffeine and camphorated oil were added as alternates. These remedies were given daily to combat the condition and later whenever there were signs of relapse, until the circulation had become permanently normal. Convalescence was normal save for the usual debility. Pregnancy was not interrupted and labor and its sequelæ were normal. A slight heroin addiction was readily overcome (the author had not mentioned that this drug had been given continually). The drug had been necessitated by the sluggishness of the respiratory center which caused recurrent attacks of dyspnea. The child was especially robust, a boy weighing 3 kilos. The lungs cleared up by slow resolution.

Il Policlinico.

Influenza, Spring and Fall.—Calo refers to the original outbreak at Modena from June 1 to June 15, which coincided nearly in point of time with the Madrid outbreak. It ran its course in fifteen days. The author refers especially to the cases in the military school. The symptoms of this mild affection are described in great detail, and agree well enough with the simple type of influenza in which fever, myalgia, prostration, slight catarrh of the respiratory tract, etc., occur. The only microorganism found in the secretions resembled the *Bacillus influenzæ*, but was not identified with it. There were but three cases of bronchopneumonia, one of which was fatal. The diagnosis made at the time was three-day fever, but, looking back, we must endeavor to distinguish between this and mild grippe. The former can now be excluded, owing to subsequent developments. There were also other elements which independently spoke for influenza, for there was no evidence of the presence of phlebotomous flies and the spread of the malady spoke for rapid man to man transmission. In October the epidemic returned to Modena and attacked the military school as before. Its character was more severe, although it was less diffusible. There were 721 victims with 23 deaths. An interesting observation was the relative immunity of the victims of the first epidemic, and also the immunity of many to both attacks. The second epidemic passed over in about twenty-two days, and was apparently preceded by a few sporadic cases. The second outbreak, while severe in comparison with the first, was still relatively mild, and differed in the greater number of complications which were almost wanting in the first. In other words, the epidemic comprised many localizing cases, so-called, in which one organ or part of one bore the brunt, as the lung parenchyma and intestines. Septic and toxemic cases were represented in small numbers.

2. Antityphoid Serotherapy: Preparation and Application of the Serum.—Rodet points out that an experimental study of long duration, pursued first by Lagriffoud, has convinced him that the serum of an immunized animal may be endowed with a high degree of specific properties with reference to the bacillus of Eberth, and still be without therapeutic value, or even injurious. Rodet has been led by degrees to group together a series of conditions all indispensable to the result sought, for the preparation and maintenance of the horses furnishing the serum. These are not simply the choice of the immunizing substance and the avenue of introduction, which have a primary importance, but also various details constituting, so to speak, the dosage of immunization. The avenue of introduction adopted exclusively is that of intravenous injection. Rodet for immunizing purposes rejects the dead bacilli, and even living bacilli cultivated on a solid media. He uses cultures in bouillon, which cultures, almost entirely reduced to soluble principles, are sufficiently toxic to kill the guinea-pig on intravenous injection in less than twenty-four hours with a dose of about 2 c.c. for a subject of 400 grams. At first the horse receives in the veins doses increasing progressively. After a certain optimum, realized in four or five months with a relatively small quantity of immunizing substance, there is a disadvantage in prolonging the impregnation of the subjects by ever-increasing quantities, or even by sustained strong doses. If this is done there is apt to be a reduction in value of the serum. Rodet avoids this by the following technique: After each bleeding the treatment is resumed with a reduced dose; the injections following are in increasing doses, in such manner that the last of the series of four to six injections may be, at least, equal to that of the preceding series. For the experimental control of the serum he foregoes the classic test by injection of the bacillus of Eberth into the peritoneal cavity of the guinea-pig as having no significance for the therapeutic value of the serum. Rodet injects the cultures, in bouillon, complete and living into the veins of the guinea-pig; the animal dies in less than twenty-four hours by pure intoxication, without bacillar multiplication and with lesions which are the same, whether with the bacilli alone, the complete liquid cultures, or the filtered cultures. The serum injected preventively under the skin in the dose of 0.2 c.c. or 0.3 c.c. ought to protect against a dose notably superior to the minimal lethal dose injected into the veins. This test betrays an antitoxic quality in the large sense of the word, which, considered in several samples of serum, is by no means proportional to the agglutinative quality, nor even to the antiinfectious quality. As for application the influence of the serotherapy may be summarized in the following formula: When the serum is administered soon enough, in the absence of established complications, in sufficient doses and at suitable intervals, in the great majority of cases it prevents the progress of the intoxication, attenuates the toxic disturbances, already existing, initiates defervescence, and, finally, shortens the duration of the disease. In order to have its full effect the serum ought to be given befor the eleventh day of the febrile period. Later the useful effects are far from being always nil, but they are inconstant and generally less pronounced. The treatment ought to begin by a relatively strong dose 15 to 20 c.c. The dose may be repeated, but very often one may content himself with decreasing doses. As a rule, three injections suffice, sometimes two; a fourth may be necessary. The interval between the injection which seems the most suitable is forty-eight hours. The happy influence of the serum is evidenced definitely by an abbreviation of the disease, at least when the treatment is undertaken early enough. In order that the serum may have its complete effect it is necessary that the typhoid infection should be free from every secondary infection. The preexistence of advanced tuberculous lesions, a simultaneous or secondary infection streptococcus, staphylococcus, diphtheria bacillus, etc restricts its efficacy. The efficacy of the serum is emphasized by the specific character of its therapeutic action. It constitutes in a certain measure a touchstone of diagnosis. The specificity goes to the point of distinguishing between the typhoid fevers properly called Eberthian and the paratyphoid infections. In these the serum is of restricted or no efficacy.

2. Notes on Radium Treatment.—Dawson Turner says stress on the fact that in recent years radium has been found consistently useful in the treatment of exophthalmic goiter. The benefit that patients with exophthalmic goiter derive from the expert application of radium is in their general condition and in their special symptoms. Thus they regain strength, lose the tired feeling, put on weight, and at the same time the tachycardia, tremor and breathlessness are diminished and may disappear altogether. The thyroid gland becomes harder and denser, but usually does not diminish in size, and the exophthalmos is but little affected. It is well to warn patients of this, lest they suffer disappointment when the neck swelling remains the same. Operative measures to reduce the size of the gland might now be considered, both because the vascularity is diminished and because the patient is better able to stand an operation. The

writer is in the habit of treating each lobe, and the isthmus of the thyroid, and the thymus. As the skin over the front of the throat appears to be very sensitive to radium rays, great care should be taken to avoid overexposing it. As compared with *x*-rays in the treatment of this condition, radium has the following advantages: 1. Absolutely constant emission of rays and therefore exact dosage possible. 2. Far greater penetration of its rays, so that the deeper parts of the gland are reached. 3. No noisy, exciting apparatus, so that the treatment can be applied at the bedside without in any way disturbing the patient. The words *cito, tuto, et jucunde* can fairly be applied to the radium treatment of exophthalmic goiter. Turner sums up the advantages of radium in the treatment of malignant disease as follows: That owing to their penetrative power they attack the deeper parts of the growth, the very roots of the disease, as well as the superficial. In proper doses they have a selective action upon the diseased tissues. Lastly they relieve pain instead of occasioning it. As to the variety of malignant disease most susceptible to radium it is admitted that sarcomas are more easily dispersed than carcinomas and of sarcomas, lymphosarcomas, in the writer's experience, are the most amenable. As for position of the growths in its bearing on prognosis, the author says that those on the surface of the body and those affecting the cervix uteri are the most favorably situated for removal by radium.

7. The Remote Results of Tonsillectomy in the Young Child.—John Zahorsky says that while the immediate results of the removal of the tonsils and adenoid vegetations is often gratifying, it is not enough to judge by the immediate results. Not sufficient studies of the remote results of tonsillectomy have been made, and this problem must be solved by the pediatrist and not by the rhinologist. Zahorsky offers a summary of the clinical observation of 150 children, aged two to twelve years, who were seen in private practice. He tried to ascertain in the study of these cases what effect the removal of tonsils and adenoid vegetations had on the nutrition and health of the child six months to five years after the operation. The opinion arrived at was that so far as the nose, ears, larynx, bronchial tubes, lungs, asthma, rheumatism and endocarditis, chorea, diphtheria, and adenopathy were concerned tonsillectomy exerted little favorable effect and in some instances did more harm than good. With regard to malnutrition, it was found that after the removal of the tonsils a large number of cases of nervous anorexia, defective growth, and slow bodily development followed. As for conferring immunity to infection Zahorsky's observations shows that the child beginning school life without tonsils is in greater danger of acute diseases than one who still has tonsils. It is at this age that the tonsils are so frequently removed simply because they are large; the physician apparently forgets that this enlargement is a physiological and probably a compensatory process. The tonsils constitute the first line of defense in the infections of the mucous membrane of the nose and throat. Clinical experience supports the view of Sonneman that the infectious material in the nose or nasopharynx that penetrates the muous membrane is carried to the tonsils. Here it is silently destroyed if the proper ferments are present. If immunity does not exist the tonsil becomes inflamed and the offending microorganisms are quickly extended, with the leucocytes and lymphoid cells, into the follicles of the tonsils. At the same time toxins and, sometimes, living bacteria enter the circulation and stimulate the production of antibodies. It is a clinical fact that an acute tonsillitis prevents the spread of a respiratory infection. The tonsil, whatever be its other functions, may be regarded as a submucous lymphatic node, and it resembles in function Peyer's patches and the solitary follicles of the intestine which also have the function of extruding bacteria, as is observed in various forms of enteritis. Zahorsky makes a plea for a conservative attitude toward the question of tonsillectomy in the young child. The tonsils should not be removed for fancied or trivial causes in a child under seven years of age.

2. Standardized Rest in the Treatment of Pulmonary Tuberculosis.—S. E. Thompson commences this paper by saying that its purpose is to present in a practical way the subject of prolonged rest in bed in the treatment of phthisis pulmonalis. He endeavors to prove the following: 1. That the word rest as applied to the treatment of tuberculosis is not standardized; that it is used to express just what one has in mind, and therefore does not mean the same thing to any two of us. 2. That complete rest in bed is just as fundamental in the treatment of the disease as it is in the treatment of typhoid fever or pneumonia. 3. That a long rest in bed is essential for healing the lungs. 4. That exercise has no place in the treatment of a tuberculous lesion, regardless of its location. Thompson points out that the views regarding rest are interpreted in different ways by the average patient and by most doctors. He thinks therefore that the word "rest" should be standardized so that no doubt exists in the patient's mind as to its meaning. He then controverts the advice given with regard to the treatment of tuberculosis in text books, including those of Austin Flint, Osler, and Thompson, that patients suffering from the disease should exercise in the open air. He is even opposed to regulated exercise and always explains to his patient exactly what he expects him to do. He does not dismiss with the advice to go to bed and rest. If symptoms are at all marked he puts him in bed, has a black cloth tied over his eyes during the day and adjures him to keep still. No reading, writing, or talking is permitted. Meals and bath are given in bed. Thompson explains to the patient why he requires this and just what it will do. As a rule the patient does not follow the course very long before the advice is found to be good and he can see the results for himself. It is argued that what is accomplished by immobilization in bed is to stop absorption. When absorption is stopped, septic symptoms disappear, the patient gets fat, and thinks he is recovering. The lesion, however, is unhealed and treatment by complete rest must be continued. When the scar tissue is formed and healing is well established the patient may get up. It is strongly urged that exercise should never be countenanced in the treatment of a tuberculous lesion, regardless of its location. The author does not wish to leave the impression that absolute rest in bed is the only essential thing in the treatment of tuberculosis. Proper food, a desirable climate, therapeutic agents when needed, are important factors; but rest in bed is fundamental in every case of active tuberculosis and should be so regarded by the medical profession.

Book Reviews.

ROENTGEN DIAGNOSIS OF DISEASES OF THE HEAD. By Dr. ARTHUR SCHÜLLER, Head of the Clinic for Nervous Diseases at the Franz-Joseph Ambulatorium, Vienna. Authorized Translation by FRED F. STOCKING, M.D., M.R.C. With a Foreword by ERNEST SACHS, M.D., Associate Professor of Surgery in Washington University. Approved for publication by the Surgeon General of the United States Army. Price $4. St. Louis: C. U. Mosby Company, 1918.

THIS is an excellent translation of a work by a German authority dealing with diagnosis of diseases and injuries of the head by Roentgen rays. The editor makes the suggestion, that wherever possible *x*-ray pictures of the skull should be made and studied stereoscopically. By studying them in this way shadows that present difficulties are readily interpreted. This book is the first comprehensive study of the roentgenology of the head published and should be of much service to specialists on cranial surgery and also to the general practitioner.

COMMOTIONS ET EMOTIONS DE GUERRE. Par A. LERI, Professeur agrégé à la Faculté de Paris. Collection Horizon. Prix, 5 francs. Paris: Masson et Cie, 1918.

THIS work is not intended alone for the neurologist and psychiatrist but makes an appeal to all practitioners alike. The subject matter appears to be comprehended under the rubric "wounded yet woundless." From the preface by Professor Marie it appears that the author devoted four years to the preparation of this book; and that it is based not only upon truth but on equity as well. The victims are characterized as "poor devils," a verdict seemingly endorsed by general experience. Throughout the work a clinical distinction is made between subjects who are, respectively, "commotioned," "contused" and "emotioned." Commotioned and contused subjects are much more easily comprehended than the so-called "emotioned" cases. The latter are complex in character and are divided into neuroses and neurasthenia. In addition there are affections secondary to both emotions and commotion. While emotional accidents pave the way for hysterical ailments, commotion, in so far as it determines organic lesions, causes symptoms which point to the encephalon, medulla, mesencephalon, and other nerve centers.

PROGRESSIVE MEDICINE—A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College, Philadelphia; assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price $6.00 per annum. Philadelphia and New York: December 1, 1919.

THIS volume contains chapters on: Diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by M. E. Rehfuss; Diseases of the kidneys, by H. A. Christian; Genitourinary diseases, by C. W. Bonney; Surgery of the extremities, shock anesthesia, infections, fractures and dislocations, and tumors, by J. C. Bloodgood; and Practical therapeutic referendum, by H. R. M. Landis. Readers will find this a particularly interesting number; the chapter on Surgery contains a most valuable résumé of some of the aspects of war surgery; and apart from this, Dr. Bloodgood's contributions from year to year show a continuity and connection which add greatly to their value.

THE AUTOMATIC FUNCTIONS AND THE PERSONALITY. By Dr. EDWARD J. KEMPF, Washington, Clinical Psychiatrist, Saint Elizabeth's Hospital, Washington, D. C. (Nervous and Mental Disease Monograph Series 28.) Price $2.00 net. New York and Washington: Nervous and Mental Disease Publishing Co., 1918.

IN this representative work of the psychoanalytical school the author considers the human organism as composed of two systems: the autonomical, comprising the sympathetic nervous system—the circulatory, digestive, genitourinary, and glandular system—and the "proficient apparatus"—the central nervous system, the bones, and striped muscles. Part I shows how anatomical construction is regulated by the autonomical system. Part II deals with the physiology of the affections. The author's theory is, briefly, that when viscera are stimulated in some manner there ensues a "postural tension," and the corresponding segment of the autonomical system likewise assumes a "postural tension"; these tensions produce sensations of desire, unrest, or incompleteness which the "proficient apparatus" relieves by causing appropriate stimuli to be received. Repetitions of this process cause fairly well-defined modes of behavior, the summation of which is personality. The author draws largely on Cannon's studies of the physiological effects of pain, fear, etc. In Part III this doctrine is extended to cover the psychoanalytical conceptions of repression, introversion, sublimation, and so on. Part IV is a recapitulation. The book is bound in heavy paper, like all of this series.

PATHOLOGICAL TECHNIQUE—A Practical Manual for Workers in Pathological Histology and Bacteriology, including directions for the performance of autopsies and for clinical diagnosis by laboratory methods. By FRANK BURR MALLORY, A.M., M.D., Associate Professor of Pathology, Harvard Medical School; Pathologist to the Boston City Hospital; and JAMES HOMER WRIGHT, A.M., M.D., S.D., Pathologist to the Massachusetts General Hospital; Assistant Professor of Pathology, Harvard Medical School. Seventh Edition. Revised and Enlarged. With 181 illustrations. Price $3.75. Philadelphia and London: W. W. Saunders Company, 1918.

THIS is the seventh edition of Sears and Mallory's Pathological Technique, a work so well and favorably known that it is superfluous to say much about it. The present edition has been rearranged and revised and certain additions have been made. For instance, the approved method of classifying pneumococci with reference to serum treatment has been included. The book is useful and practical, and easily ranks as one of the best of its kind.

STUDIES IN ELECTRO-PATHOLOGY. By A. WHITE ROBERTSON, L.R.C.P. and S.E. Temp. Major R.A.M.C. Illustrated. Price $5. New York: E. P. Dutton & Co.: London: George Routledge & Sons, 1918.

PHYSICAL science is still in its infancy, but we are daily learning more concerning the elementary facts which have determined the life, reproduction, and decay of animal and all other matter which exists on this globe. The object of the physician is to ward off death from members of the human species, and according to the writer of this book physical science harnessed to the service of man is best adapted to achieve this end. The book is an account, of how electricity or rather the electric potentialities of the body, can be employed in surgery and medicine. The work is interesting and suggestive.

TEXT-BOOK OF CHEMISTRY INORGANIC AND ORGANIC, WITH TOXICOLOGY. For Students of Medicine, Pharmacy, Dentistry, and Biology. By R. A. WITTHAUS, A.M., M.D., Late Professor of Chemistry, Physics and Toxicology in Cornell University. Seventh, Revised Edition. By R. J. E. Scott, M.A., B.C.L., M.D., Fellow of the New York Academy of Medicine; Editor of "Witthaus' Essentials of Chemistry and Toxicology," etc., etc. Price $4. New York: William Wood and Company, 1919.

THIS work on chemistry possesses such great sterling merit and is so firmly established in favor as a students' text-book that praise is superfluous. However, this the seventh edition has undergone a considerable amount of revision rendered necessary by changes in the medical curriculum before it was brought into its present shape. For this revision Dr. R. J. E. Scott, the editor, is responsible, and he has succeeded admirably in keeping the size of the book within reasonable bounds and at the same time including all the information that is necessary to the education of the student in this particular branch of science. A good deal of the old matter has been excluded for one sufficient reason or another, and the work in its present form contains little or nothing that is not absolutely essential in a text-book of this description.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 20, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

Report on Prevention of Influenza of the Public Health Committee of the New York Academy of Medicine.—Dr. CHARLES L. DANA submitted this report. (See page 516.

The Dangers of Secondary Infection in the Ward Treatment of Influenza and Pneumonia.—Captain FRANCIS G. BLAKE, M. C., U. S. Army, presented this communication, in which he stated that one of the most pressing problems that presented itself in the care of influenza and pneumonia patients in our army cantonments during the recent epidemic was the danger of secondary contact infection because of the overcrowding of the base hospitals, nearly all of which had been taxed beyond the limits of their capacity. In their experience at Camp Pike it was found that a very large percentage of the pneumonias following influenza were caused by a secondary infection with pneumococcus, some few being caused by hemolytic streptococcus. The types of pneumococci encountered were almost entirely those that were normally found in the mouths of healthy men, approximately 85 per cent. being Types IV (II atypical), and III. It had been generally accepted that infection with these types of pneumococci was usually autogenous. Observations made during the course of their work had suggested that this was probably not so in most instances and that the patient was not so much in danger from his own pneumococci as he was from that carried by his neighbor, in other words the danger was from contact infection. The same consideration held true with respect to hemolytic streptococcus infection. Secondary contact infection in cases of already existing pneumonia were also found to occur frequently. That contact infection played a very important and serious rôle was brought out by bacteriological studies made during life and at autopsy upon cases in the wards of the hospital. Charts showed the comparative death rate from pneumonia, on one hand, in wards which had long been organized for the care of patients with pneumonia and, on the other hand, in wards which were opened for patients with pneumonia and immediately overfilled at a time when the hospital was overwhelmed by the epidemic of influenza. An inspection of the tables showed that the death rate from pneumonia gradually increased as the ward became more and more crowded. This might be attributed in part to the increased severity of the pneumonia during the early days of the influenza epidemic. A detailed study of various wards was presented which showed that streptococcus infection might spread by contagion throughout an entire ward. Other observations had demonstrated that pneumococcus infection might be transferred in the same way. Three instances of secondary contact infection with pneumococci were cited which occurred in wards where every precaution was supposedly taken against the transfer of infection from one patient to another. Numerous other instances of secondary pneumococcus infection were met, nearly all possible combinations of different types of pneumococci being found. This was a condition almost never encountered in pneumonia patients treated under the conditions of civilian practice in normal times. While the data presented dealt with contact infection in cases of pneumonia, similar, though less extensive studies had shown that the same general considerations held with respect to secondary contact infection when cases of influenza were treated in crowded hospital wards, the incidence of pneumonia being proportional to the opportunity presented for the dissemination of pneumococci and hemolytic streptococci. The methods in vogue for preventing the spread of contagion in wards devoted to the care of influenza and pneumonia patients consisted in the separation of patients by means of sheets hung between the beds, the wearing of masks and gowns by the ward personnel, and to some extent by convalescent patients who were up and about the ward, and in some hospitals the separation of streptococcus carriers from non-carriers as determined by throat culture at the time of admission. That these methods might be of some value in preventing the spread of infection could not be denied, and it was probable that they would be fairly effective under ordinary conditions, when conscientiously carried out. That they inevitably broke down in the presence of an overwhelming epidemic was only too evident. Sheet cubicles were not proof against a patient's curiosity as to the identity and condition of the man in the adjoining bed; masks could not be worn by patients seriously ill with pneumonia, the very time when they were most dangerous and in greatest danger; the separation of streptococcus carriers from non-carriers could not keep pace with the ever increasing influx of patients nor with the rapidity of the spread of the hemolytic streptococcus, because of the time required to make the bacteriological diagnosis. Not only did these methods break down in the face of an epidemic, but they often provided a false sense of security that did not really exist. In searching for the solution of the problem it was essential to have clearly in mind that every patient with influenza must be considered a potential source of pneumococcus or streptococcus infection for his neighbor; that every person engaged in the care of patients with respiratory diseases must also be regarded as a potential source of danger; that pneumonia could no longer be regarded as one disease but must be looked upon as a group of different diseases, with similar physical signs and symptoms, it was true, but caused by a great variety of bacteria, infection with any one of which not only provided no protection against infection with another, but might even render the individual more susceptible to secondary infection. Since secondary infection in respiratory disease was undoubtedly spread in large part by droplet and contact infection, the prevention of secondary infection must depend upon the elimination of these methods of transmission. Two solutions presented themselves, either segregation of patients according to type of bacterial infection, or effective individual isolation of all patients. Segregation according to type of infection in the presence of an overwhelming epidemic was obviously impossible since one could not make an immediate diagnosis of the type of infection by inspection of the patient, and the time required to make a bacteriological diagnosis defeated this purpose. In view of these considerations it was believed that the clear and most fundamental indication for the management of epidemic respiratory diseases, not only in the army but in the civilian population, was to scatter patients as widely as possible, instead of following the time honored custom of concentrating them. In brief, ward treatment should be abandoned and effective individual isolation of every case adopted.

The Treatment of Influenza and Bronchopneumonia by the Use of Human Serum.—Lieutenant WILLIAM R. REDDEN, M. C., U. S. N., of the United States Naval Hospital, Chelsea, Mass., read this paper, in which he stated that in a preliminary report Dr. Maguire and he presented data of 37 cases of bronchopneumonia, following the epidemic of so-called influenza, treated with serum obtained from patients recovered from a similar pneumonia. The present report gave as complete data as were obtainable on 151 cases at the Naval Hospital at Chelsea. This represented all cases of the above type admitted to the hospital from September 27 to January 1 and included the original 37 cases reported. In their preliminary report they had noticed that the severity of the disease was on the wane and they naturally wanted a field to carry on the work in which the severity of the epidemic was unquestionably great. After several futile attempts there came to them a group of men from the U. S. S. *Yacoma*, in which the incidence of influenza, the complicating pneumonia, and the severity of the infection appeared quite comparable with the situation at the beginning of the epidemic. Hence this group were considered in the total and also separately. In addition to the *Yacoma* group 80 cases represented the latter part of the first epidemic, whereas the remainder represented those in the December recrudescence of the epidemic where the severity of the disease was undoubtedly great, though somewhat modified. Most of the cases received serum treatment within the first four days of the pneumonia,

and the majority received it within the first forty-eight hours. Three injections of the serum were sufficient in 132 cases, two-thirds of these required only two injections, and one-third but one. The majority requiring more than one injection had advanced at least three days in their pneumonias. The average amount at each injection was 120 c.c. As to the immediate results of the injections, in about 5 per cent. of the cases a chill occurred coming on from 10 to 30 minutes after the administration of the serum. This was associated with a rise in temperature, pulse, and respiration, but never amounted to so much as reactions from horse serum, there being no latent reactions such as urticaria. In from two to twenty-four hours the patient showed signs of decided improvement. The toxic symptoms such as nausea, vomiting, vasomotor disturbances, and irritative cough, if present, disappeared along with the headache, etc. The anxious expression of a sick patient was transformed to that of a convalescent. The temperature, pulse, and respiration fell, the temperature and pulse reading normal before the respirations fell. In this series of 151 cases 83 had a normal temperature within 24 hours and 135 within three days; 51.7 per cent. in three days or less irrespective of the amount of lung involvement; 85.6 per cent. were normal in five days or less. This was a decided shortening of the course of the pneumonic disease. The length of time the lung disease persisted after the temperature reached normal varied according to the amount of lung involvement and the time of the pneumonic complication when the serum was given. Those cases which received the serum early in the disease before extensive consolidation occurred cleared more readily, while in those treated later in the course of the disease the signs persisted, a week, two weeks, and sometimes a month. This persistence of the signs of consolidation which were frequently more the signs of fluid, was one of the striking features of the disease. A study of the blood count showed that the majority of these bronchopneumonias had either a normal count or a leucopenia. It was noteworthy that all cases that did not respond readily to serum treatment were included in the group having high white counts, although many with high white counts did respond readily. The above group also included all who showed the hemolytic streptococcus complication. Complications in this series had been infrequent. Lieutenant Redden insisted on the prime importance of proper diagnosis in the matter of serum therapy, and stated that the clinical onset of lobar pneumonia was usually quite different from the influenzal in onset, being characterized by a high white count. They had typed all the sputa from the pneumonias with a high white count and suspicious history and they felt that few if any lobar pneumonias had remained undiagnosed, but the differentiation between the hemolytic streptococcus and the influenzal pneumonias was difficult, though not impossible. Sputum from low down thoroughly washed usually gave a pure culture or a predominating culture of hemolytic streptococcus if the pneumonia was of that type. Then a dominant sore throat was also suggestive of this type of pneumonia. Moreover, a chest tap in nine cases out of ten would yield fluid, and in the tenth case one would get blood showing pure cultures of the hemolytic streptococcus, a picture quite different from the influenza bronchopneumonia. It had been their desire to run parallel control groups without the serum treatment, with treatment with normal human serum, and with treatment by the use of serum from those having influenza without lung complications. For obvious reasons they had been unable to let patients with the pneumonia complications go on without serum treatment. However, a few cases were treated as controls or partial controls, and the results in such cases seemed to be in harmony with those obtained in the group receiving the serum treatment and seemed to confirm the conclusions as to the value of the convalescent serum treatment. Careful blood examinations were made in 130 cases and from the data obtained it was evident that that a low white blood count was characteristic of the usual bronchopneumonia following influenza. Hence it was of prime importance to get the blood count before instituting serum therapy. The extent and distribution of lung signs could not be used to distinguish broncho- from lobar pneumonia, for it frequently happened that the broncho gave signs of lobar. A low respiration and low pulse rate compared to the lung involvement and high temperature aided in making a diagnosis of the former. At the present time the only method of testing the potency of the convalescent serum was by its effect on the patients. From their observations it might be safe to say that the serum had some antitoxin action. Beyond this they believed that discussion was futile at the present time. The mortality rate of this series of 151 cases of influenza pneumonia was 4 per cent. Three of these deaths were due to streptococcus pneumonia after the patients were recovering from the influenza pneumonia. This death rate was apparently directly due to the proper use of the serum. Their records had been examined by the State Commissioner, Dr. Frederick Lord, who had recommended the establishment of hospital centers to carry out this treatment.

Dr. Rufus Cole said that the papers of the evening had touched on the whole field of acute respiratory disease, including influenza. This made the discussion of the various problems concerning respiratory infections very difficult, since knowledge concerning influenza was so fragmentary and opinions held by various observers were so divergent. If one read the older literature concerning influenza, he found that the discussion which accompanied each epidemic was almost identical with that which one heard today. There was one striking difference, however. Today there was little opposition to the view that it was an infectious disease. Moreover, most persons now agreed that it was a communicable disease, transmitted largely by personal contact, even in spite of the failure of the experiments which had been made to transmit it artificially from person to person. It seemed that, having accepted these views, the next step would follow as a matter of course; that was that an attempt should be made to isolate the patients sick of the disease, since from what we knew of other infections it seemed likely that the infectious agent existed in its most virulent and concentrated form in the persons sick of the disease. These principles would seem to apply not only to influenza, but also to all acute infections of the respiratory tract. The epidemics of influenza occurring every thirty years or so were not isolated phenomena. Last winter there occurred a considerable epidemic of respiratory infection in this city and this country due apparently to virulent hemolytic streptococci. Lesser epidemics of pneumonia we had every winter. If these infections of the respiratory tract were spread by personal contact, the first step in prevention would seem to consist in isolating those sick of the disease. Isolation of carriers or the prevention of carriers from spreading the disease was another matter, obviously more difficult. Because this could not be done, however, was no reason why an effort should not be made to carry out the other more simple procedure. Patients having smallpox, scarlet fever, or pneumonic plague were isolated as a matter of course, but persons suffering from acute respiratory infections were allowed to spread the disease by sneezing and coughing, even though this latter kind of infection might be more serious than the former, as the recent epidemic of influenza shows. In order that such measures of prevention as the speaker had mentioned might be undertaken, however, it was necessary that we have definite and convincing proof of the contagious nature of these respiratory infections, and Dr. Blake's work was of very great importance since it brought additional and convincing evidence. In regard to the treatment of influenzal pneumonia by the serum of convalescents, Dr. Redden had started with certain assumptions in regard to the nature of the infection. If the results which he had presented tonight concerning the efficacy of serum were confirmed, his assumption would probably be proven. At the present time, however, there was a great difference of opinion in regard to the nature of the pneumonia occurring with influenza. He thought most observers believed that the pneumonia was due to secondary infection, and that by the time this stage was reached an immune serum which would neutralize the effects of the primary disease would have little effect. It was to be hoped that Dr. Redden will continue his observations and that others who had facilities for carrying out this method with proper attention to detail and with opportunities for accurately recording observations might also inves-

tigate this method of treatment. He supposed Dr. Redden would be the last one to assert that the value of the method of treatment had been finally proven, or that he would desire that the method should be carried out at the present time indiscriminately, in a routine and uncontrolled manner.

Dr. Morris Manges, referring to the treatment of influenza with convalescent serum, said he could only envy Dr. Redden the privilege of working in a military hospital where he was not hampered by the disadvantages that were met with in attempting to carry out the treatment with convalescent serum in civil hospitals and private practice. Those who had tried it had met with the difficulty of getting blood. He had treated hundreds of cases of influenza and he could recall only one who was willing to give his blood; and others who had wished to carry out this treatment had had similar difficulties. At a military hospital blood could be obtained easily and was of all varieties, from very poor to very rich in antibodies, so that a very good pooled blood was easily available. Therefore those present could not corroborate what had been said by their personal experience. He believed, however, that this work represented a great advance in the right direction, because Dr. Redden was not treating symptoms but was treating the disease itself. It was undoubtedly the treatment of the future. It was, however, a pity that some method could not be devised to get the serum from a lower animal; but as it has been impossible to experimentally infect human beings, and the specific cause being unknown, it would be at present impossible to obtain serum from lower animals. When one listened to these reports from the military hospitals the accounts of the overcrowding made one shudder at the horrible picture. He mentioned this not in the way of criticism, but in a tone of regret that such conditions could not have been avoided. It was a pity that they could not have more hospitals with porches instead of wards, and that brought up a point in Dana's report, namely, that he felt it was unfair to say that those treated in the hospitals of the city during the epidemic of influenza were not as well off as those treated in their own homes. He felt that, with the scarcity of nurses and of domestic help and the poor quality of the nurses, that the patients received much better care in the hospitals and that the hospitals were not unduly overcrowded. Dr. Redden had attempted to differentiate the *Streptococcus viridans* infection from the other kinds of infections by stating that it was usually accompanied by a sore throat, but in cases of influenza, sore throat was present long before the viridans made its presence known. In the pneumonias seen during the epidemic the number of empyemas had been singularly small, and the number of cases complicated by pleurisy with effusion had likewise been small. As to the question of the classification of lobar and lobular pneumonias and their differentiation, this was a question of physical signs and not a real pathological difference. Finally, he would like to say that the continuation of the signs of consolidation was not due to fluid, for he had tapped and fluoroscoped many of these patients and usually had found no fluid; it was due most frequently to interstitial changes in the lungs, a point to which Dr. Delafield had called attention many years ago, and which Dr. Symmers had recently emphasized.

Lieut. E. W. Gould, M. C., U. S. N. R. F., of the Naval Hospital, Brooklyn, said that since last September they had treated, under the jurisdiction of the United States Naval Hospital at New York, 842 cases of pneumonia, 320 having come under their immediate supervision at the Naval Hospital. The others were sent to civilian hospitals that had so kindly assisted them in caring for the great number of sick and wounded brought to this port. The mortality rate among the 320 cases treated at the Naval Hospital was 26.16, but in connection with this mortality rate the fact must be taken into consideration that on account of their limited accommodations all cases diagnosed as influenza were sent to civilian hospitals, although a large number of these cases undoubtedly had pneumonia at the time or developed it later. Statistics in regard to pneumonia were very misleading. Last spring during the months of February, March, and April their mortality was a little over 21 per cent. In May and June they ran a series of eighty-five cases without a death, although practically the same lines of treatment were pursued. At the beginning of the influenza epidemic in September, when they received pneumonia cases only, their mortality rate was 50 per cent.; at the end of the epidemic it had dropped to about 10 per cent. This was about the time when they began the use of the human serum. Recently they had had a much higher mortality rate, due, it was believed, to a different infecting organism. Thus it might be seen that from month to month the kind and virulence of the infecting organism, and perhaps the immunity of the individual, varied greatly. The results of their treatment in the early cases of influenza-pneumonia in September were so discouraging that they most gladly welcomed Dr. Redden's method which was proposed at that time. They ran a series of about thirty cases of apparent influenza type which were treated by the use of human serum from convalescent cases, with a loss of only two patients. While the low mortality was perhaps not so striking owing to the fact that the death rate had already begun to drop, they felt that the immediate and remarkable response in many of these cases could be attributed only to some specific antibody that was injected. They felt warranted at that time in concluding that they could materially, if not completely, modify the course of the disease in most of these cases by the use of the human serum. During the recent severe epidemic they had experienced the same difficulties that had been met with elsewhere. Many of their cases had presented clinical pictures simulating influenza-pneumonia very closely, showing the characteristic early depression, cyanosis, and leucopenia, but giving no response to repeated injections of human serum. Many of these cases had been later shown to be cases of infection with the *Streptococcus hemolyticus*, and on account of the severe general toxemia, the frequent development of empyema and pleurisy, and the unusually severe pulmonary hemorrhages, they believed that the *Streptococcus hemolyticus* played a more important rôle than they were always able to demonstrate. They did not feel justified in puncturing the lung for diagnostic purposes only. Inasmuch as this differential diagnosis could not be made in the early stages of the disease, and they felt that the treatment should be begun at the earliest possible moment, the mortality rate of their cases treated recently with the human serum had been very unsatisfactory. They had included in this list all those who had received even a single dose of the serum and their mortality rate among all those so treated during the past two months had been 26 per cent. During the last epidemic they had at first tried to select their cases and to use human serum on those cases only that were very probably influenza, using Type 1 and sometimes polyvalent serum on those that could be typed. They soon found, however, that their bacteriological results were not very reliable and that even those cases that had a leucocytosis and a sputum that would type showed upon postmortem examination a lobular consolidation with that peculiar, serous bloody exudate, so frequently spoken of as hemorrhagic pneumonitis. It seemed likely that the influenza bacillus as well as the streptococcus organism was a frequent offending agent with the pneumococcus. During this whole season they had not more than two or three cases examined post-mortem that showed the characteristic red or gray hepatization of the ordinary pneumococcus infection. They had, therefore, been using recently as donors many of these cases of pneumonia which had previously had a leucocytosis and even some of those whose sputum had been typed, and had noticed that excellent results were apparently obtained with the blood of some donors who had shown a moderate leucocytosis during their previous attack. It was quite possible that they might thus be using a serum from a case of mixed infection, including the influenza bacillus and the *Streptococcus hemolyticus*, and that the serum contained valuable immune bodies for homologous strains, but would not protect those infected with a strain serologically different. In using the human serum they had not employed the pooling method, but had endeavored to match the donors and recipients as far as possible. They had no reliable way of measuring the potency of any serum, but had frequently been struck with the remarkable results obtained from the use of cer-

tain donors. They had not been able to confirm the contention of Dr. Redden that the amount of lung involvement in the donor was necessarily a reliable criterion in determining the value of his serum, although they believed in general that it was of some importance. As a result of their work they had been impressed with the belief that the human serum from convalescent pneumonias undoubtedly contained valuable antibodies and that its use in cases infected with homologous strains would give satisfactory results, but with their present limited ability to definitely isolate the infecting organism of the donor and the recipient the method could not yet be placed upon a practical basis where definite results could be reasonably expected. Furthermore, this method could not be used except in a large, well equipped hospital, where access could be had to many willing donors. They had had no bad results from the withdrawal of 400 c.c. to 500 c.c. of blood from the donors at each of two sittings, at intervals of two or three days. They, of course, did not use the donors until their temperature had been normal for two or three days. In no case had they seen any untoward effect from the injection of the serum.

Dr. Dudley Roberts stated that during the tragic days of the first and second weeks of October everyone had been deeply interested in Dr. Redden's first report of the treatment of influenza pneumonias with transfusion. At U. S. Army General Hospital No. 1 transfusion was tried only a few times with unsatisfactory results, but it was only fair to say that it was not used as an early routine measure, but reserved for the obviously severe cases. He questioned whether the results which Dr. Redden had secured were in fact due to the conferring of a passive immunity from the blood of recovered cases rather than the result of the phenomena of "non-specific protein reaction." It seemed hardly possible that through an attack of the disease a transferable immunity could be established unless enormous amounts of blood were used. Dr. Roberts referred to the fact that at the October meeting of the Academy he had recounted their experience at Base Hospital No. 1 with the intravenous injection of mixed influenza vaccines. At that time the series of cases so treated was not large and the results were more problematical than they became later. They ultimately satisfied themselves that the good results came in those cases in which there was a definite reaction. Two consecutive series of cases were studied, those in the first series, treated by an expectant plan, 86 in number, showed a mortality of 31.3 per cent., while the patients in the second series, 200 in number, up to the middle of November, who were treated by intravenous vaccine injections showed a mortality of only 9.6 per cent.

Lieutenant Redden, in closing the discussion, said that a man in Boston had told him that he could not use the serum treatment in private practice and his reply to that statement would be made when he reported, as he hoped to do in about a month, on seventy-six cases in private practice treated with convalescent serum. In treating these cases he had done all the work himself, withdrawing the blood, preparing the serum, and making the injections. In doing the work he had used only the simplest apparatus and not the complicated apparatus shown this evening. He, therefore, hoped to show that it was entirely practicable to employ this method in private practice. The reaction was not a non-specific protein reaction in the sense just mentioned. He did not look for a chill and in over 600 injections had only about four chills. The result of the injection was not a rise in temperature, but a drop. In the use of non-specific protein there was usually a fall of temperature after a rise, then a secondary rise. As to the etiological agent responsible for the disease, he did not know what it was, but he felt that since they had a group of cases with similar signs and symptoms and a practically similar bacteriology, and since the changes shown at autopsy were the same, and the changes produced by giving the serum were the same, thought that he was fully justified in assuming that they were dealing in all these cases with a similar disease. His positiveness was only apparent, he said, being due solely to the attempt to present as much proof as possible in the short time at his disposal.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, February 5, 1919.

The President, Colonel William J. Taylor, in the Chair.

Concerning Concussion and Contusion Injuries of the Eye in Warfare.—Lieutenant Colonel George E. de Schweinitz in this communication dealt mainly with some of the results of ocular concussion and contusion in warfare, and made mention of some of the pathogenetic problems which they presented, of certain of the differences which were evident as compared with the results of such injuries in civilian life, and of one or two new clinical pictures. A large literature was said to have accumulated on the subject, and at least two important atlases had been produced, one by Lagrange and one by von Szily. Colonel W. T. Lister of the Royal Army Medical Corps had made notable contributions. In general terms Colonel de Schweinitz said that the fundus lesions under discussion were caused *directly* by a blow or sudden forceful pressure on the eyeball, behind, from the side, or tangentially; or *indirectly*, by the transmission of concussion or shock (contrecoup). In the first instance the lesions were classified as lesions by contact; in the second instance, as lesions by concussion. The contact lesions were said to be caused by a missile which grazed the globe but did not rupture it, or by a fragment or portion of a fractured orbital wall or floor or roof thrust harshly against the eyeball. The concussion lesions were caused by (*a*) concussion at a distance; (*b*) transmission of concussion or shock through the bony facial structures; (*c*) slight blows on the anterior part of the eye, the concussion being transmitted through the transparent media to the posterior pole (Lagrange). The lesions might be summarized as (1) lesions by concussion; (2) lesions by impact; (3) combined lesions, *i.e.* by both concussion and impact. Should the lesions of the inner membranes result from a concussion at a distance, their development was attributed to the commotion of the air-column shaking the ocular wall in the same manner as it shakes the door of a room. Should the concussion waves reach the eye in a line of transmission through the bony facial structure, the effect was likened to the lifting up and shaking of a ship by a ground swell, and the entire adipose envelope was concussioned, resulting in ruptures of the inner ocular coats (Lagrange). Of external manifestations there might be none at all; therefore routine ophthalmoscopic examination of the eyes of wounded soldiers should be made. The statement that lowered eyeball tension is an important sign of perforating scleral wounds must not, the author said, be taken unreservedly, in view of the many observations in this war. Notable were the cases of injury of the optic nerve in the canal by a missile passing through the orbit posteriorly, which sometimes cut across the nerve, or the nerve was injured by a radiating fracture of the orbit. Mostly the result was an irremediable atrophy of the nerve and blindness. Avulsion of the optic nerve, when an eye was jerked from its socket, was not infrequent. Contusion and concussion injuries of the eye in this war which had followed oblique wounds of the facial bony structures had represented about 6 to 8 per cent. of the whole number. There seemed very little doubt that lesions of the inner eye by concussion from a distance, by concussion transmitted through the bony facial structures and following blows on the point of the eye, were located by preference in the macula and paramacular area; that impact lesions were equatorial and always adjacent to the site of contact; that a contact lesion might spread toward the center; that posterior pole and equatorial contact lesions might approach and join each other; and that missiles traversing the structures behind the bulbus and radiating fractures of the orbital vault were responsible for most of the direct optic nerve injuries. Whether it was safe to say that impact lesions were always, or almost always, retinochoroidal and concussion lesions choroidal, as Lagrange contended, it would seem was not definitely settled. In the hope of stimulating the absorption of extravasated blood and exudation, the usual alterative, diaphoretic and lymphagogue remedies might be tried, as might electricity, especially for those eyes with much vitreous

change. Thyroid extract was also employed. Colonel de Schweinitz was frankly skeptical whether remedial agents had much influence, and more than skeptical as to the value of subconjunctival injections. In a certain number of apparently severely concussioned eyes, notable improvement in vision had occurred after long periods of time. Transitory astigmatism after direct concussion had often been noted. (The paper was illustrated and the various types of concussion and impact injuries portrayed by means of a series of diagrams taken from Lagrange's and von Szily's Atlases, and some water colors by the late Miss Margaretta Washington of concussion injuries in civil practice. Drawings which are to be made of the fundus lesions studied in the various American "eye centers" were not at the time available.)

Captain GEORGE H. CROSS said that the markedly interesting picture presented in the ophthalmological service in Hospital No. 11 at Cape May was the enormity of the hemorrhages or involvement of the fundus which masked temporarily the true condition. A long time after the injury there would be the appearance of a rupture, but it was difficult to tell whether there was atrophy or rupture of the structures beneath. They had three cases of so-called "holes" in the macula, all due to injury of the skull and not directly to the eye. Another type was observed in the case of a soldier with a piece of shrapnel about a centimeter square in the median line of the sphenoid, which penetrated straight in without injuring either eye directly, although the visual fields were most unusually contracted. Externally the eyes were perfectly normal. In other cases the missile had struck the antrum, injuring the orbital rim and floor. While the eyeball showed no external evidence of injury, rare fundus conditions were found internally. In some cases the orbital rim and parts of the bony wall had been torn away, but without injury to the eyeball itself, except displacing it from its normal position. Examination showed that there might be only light perception, with this peculiar condition of the fundus; in others a surprisingly large percentage of vision was retained. In one soldier the foreign body, while not injuring the globe directly, struck the rim of the orbit, traveling along the nasal side, finally lodging in the orbital fat. The patient stated that when struck he had become temporarily blind in both eyes; that in three or four days he began to recover vision in the right eye; when he arrived at Cape May the picture was that of a fine granular pigment in a triangular area below the disc, with no other evidence of injury. There was a perceptible diminution of vision in an area corresponding to the pigmented area noted in the fundus, but no scotoma was found, and no other pathological condition.

Reeducation of the Blind Soldiers.—Lieutenant Colonel JAMES BORDLEY, Director, Red Cross Institute for the Blind, Baltimore, Md., stated that in an investigation of the wage-earning pursuits of the civilian blind it was shown that the vast majority of the 85,000 blind in this country were dependent, in part or in whole, upon their friends or the State; that in 100 cities 43 per cent of the professional beggars were blind people; that the average wage of conscientious, willing, working blind men was about $4 per week and that of the same type of blind women about half as much. Blind people, he claimed, had a very definite economic value when properly trained. More money, he said, was wasted each year in foolish charity than would be required to train and place our whole blind population. Few people knew that there was not a single school in the United States for the vocational training of the adult blind; that there never had been devised a scientific scheme for their education and training, and that not a single normal school trains teachers for the blind. The medical profession was not altogether blameless for the mental deterioration of many blind people; through mistaken sympathy the blind were kept in ignorance of their real condition. The attitude of the family was often a most serious drawback to their occupational development. The attitude of the public, he felt, was responsible for much of the trouble of blind people, and it was primarily to overcome this attitude that St. Dunstan's in England and Evergreen in this country were opened. They were not schools in the narrow sense, but rather universities, where the blind were taught hope and courage, trades and professions, ambition and success. The men there were not "poor dear blind boys," but strong, resolute, normal men expecting to win. The courses of instruction at Evergreen were divided into recreational, essential handwork, and vocational. The blind man was said to have more difficulty learning to play than to work, and for this purpose music, dancing, bowling, swimming, gymnasium exercises were available as indoor activities, and field events as outdoor sports. Included in the essential handwork was typewriting. Another essential study was the raised dot type of the blind—Braille. The usual schemes for developing the sense of touch were taught. As occupations of profit there were taught bookbinding, telephone operating, massage, and other industrial and commercial subjects. Included in the commercial course was the application of an experimental store, the advance agent of a chain of stores to be operated by and in the interest of blinded military men. The experimental store in size, color, shape, and fixtures was the model that had been adopted for all the stores, and from this experimental store at Evergreen the men would be transferred to experimental stores in the business section of Baltimore. These stores were to be called "The Victory Stores," meaning the defeat of gloom, despair, and affliction by the blind man himself. The plan for teaching industrial work for the blind had been evolved by having an industrial engineer make a survey of industry and by a process of elimination it was readily discovered what jobs the blind could best fill.

Research Work on the Problems of Aviation.—Major WALTER B. LANCASTER of Boston said that for the study of the problems of flight the visual function might be divided into the purely sensory or percipient, the adjusting mechanism, and the psychic side of vision. Sensory functions withstood the strain of asphyxiation and fatigue without breakdown. Under this head were the retinal functions of light sense, color sense, form sense. The adjusting mechanisms were three: Fixation, focusing, adaptation to light. These were rather complex functions, and likely to break down under strain; whether they would or not in a given case depended upon whether any defect was present, and on how well the defect was compensated, some defects being better compensated than others. To insure the best compensation the mental and physical conditions must be maintained at their best, hence the importance of the "care of the flier." The psychic side of vision included stereoscopic vision and various matters of judgment and discrimination based on visual perception. They were not much affected by asphyxiation and fatigue. Investigations were being carried on regarding stereoscopic vision, and other methods of estimating distances at long range, as to light, sense, and adaptation, as to accommodation speed, and as to the relative value of different ways of measuring heterophoria. The motion pictures from the Mineola Laboratory which were shown illustrated the problem of the blind angle and the way things look to the flier.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, February 12, 1919.

THE PRESIDENT, DR. B. FRANKLIN STAHL, IN THE CHAIR.

The Work of the Health Insurance Committee of Pennsylvania.—WILLIAM DRAPER LEWIS, Esq., Dean of the Law School, University of Pennsylvania, in describing the work of the Health Insurance Committee of Pennsylvania appointed two years ago said it had made a survey of typical but different districts of this city, of country districts, and of other cities of the State, gathering certain facts regarding the quantity and the economic results of sickness among wage earners. Having this knowledge it had sought to ascertain the various plans in operation abroad or which had been suggested at home and find a solution of the problem encountered. The two main results of the investigations were that the actual amount of sickness in the community among wage earners and the days lost, the estimates running from 20 to over 50 per cent., were very much increased by the fact that the wage earner could not afford to lay off when he was sick. The his-

tory of one case after another was that a man who was sick kept on his feet with the result that the sickness which might have been of only short duration became a long and serious one. From the survey made in Kensington it had been found that while many workmen were not sick, the average number of days lost by the men was 36 days in the year. The charitable organizations helping the commission showed sickness to be the greatest single cause of poverty and destitution, the estimate being between 40 and 60 per cent. This condition obtained in the family of the man who was steadily employed but who could not afford to be sick. The problem presented was typical of the case of "John Callahan." This John Callahan was employed by a large corporation, had married young and had several children. He was a sober, industrious man and received good wages from the standpoint of similar work, sufficient to provide his family with nourishing food and to enable him to save a little money. John Callahan, however, could not afford to get sick, and when he did get sick all his savings disappeared. The doctor who had been attending him, who had been paid very little or not at all, continued to come; the grocer allowed him to run up bills, and the doctor and the grocer carried the load. Then Mrs. Callahan got sick and after this the children, from being underfed; the family ran down hill until Mrs. Callahan took the young child to the hospital. Then it was that through the Social Service the family was restored to a self-supporting position. That "John Callahan," though alive to-day and at work, would never do a full day's work again. Emphasis was placed upon the fact that the loss of wages, the result of sickness, fell upon the one man in the community who was least able to bear it. The question asked by the State of the Health Commission was: "Is there any remedy for the problem of 'John Callahan,' any machinery of the State by which the incidence would not fall upon him, by which when he was sick he could get adequate medical care decently paid for? In Europe it was believed that the problem had been solved. The author did not say that the system of England was right; nor that any particular insurance was right. What he would say, however, was that the economic loss from sickness must be removed from "John Callahan," if there was to be removed the destitution which doctors, more than the average members of the community, were paying for. The problem, he said, was a big administrative one which affected the medical profession more than any other. He expressed the desire that societies such as the Philadelphia County Medical Society appoint representatives to work with the committee in trying to find a working practicable plan. He did not think any great insurance plan which would cover millions of people would ever be a practical success unless through it the medical profession were rightfully compensated from the point of view of members of the profession. A plan by which the medical profession ceased to carry the burden which it was now largely doing was essential. It was no more right that such burden should be carried by the physician than that it should be borne by John Callahan. In his opinion it should be carried by the community in part, by John Callahan in part, and perhaps in part by the employer. He believed that any important service in the community should be paid for adequately; otherwise the community suffered.

Health Insurance as a State Policy.—Dr. JOHN B. MCALISTER of Harrisburg said that it was not his intention to present any arguments for or against health insurance as a State policy, but rather to present the sickness problem as developed by the investigation of the commission. Sickness, he said, produced a problem between five and seven times as great as that caused by industrial accidents. In 1916 3,025,375 working days were lost in Pennsylvania through accidents, while approximately 16,800,000 working days were lost on account of illness. Among the facts obtained through investigation, it was noted that more than 385,000 employees in the State were constantly suffering from illness, and that the average loss of working time to employees in the State was at least six days each year because of sickness. At the nominal rate of $2 per day the wage loss to employees because of illness was thus at least $33,000,000. The average cost of medical care for every employee's family was between $30 and $50 per year. During the influenza epidemic anthracite coal production dropped behind 500,000 tons in a few days. The statement was made that the State spent over $6,000,000 every year directly for the treatment of sickness. In addition, $4,000,000 was spent for the maintenance of institutions for the care of defectives, due partly to the neglect of sickness. Sickness seemed to be the principal single factor forcing the wage earner's family to seek help. It was the primary cause of dependency in 50 per cent. of 5,000 cases studied in California and 42 per cent. of the 1,141 cases in New Jersey. In Pennsylvania the same general conclusions were borne out. The present facilities for medical care among wage earners were shown to be not satisfactory. The number of beds per one thousand population was three and one-tenth. Authorities said that five beds per one thousand population was necessary. Sixteen of the sixty-seven counties in Pennsylvania were said to have no hospital beds and nine other counties had less than one per thousand persons. When the cost of ward beds was beyond the means of probably half the employees of the State, when in a single year nearly 2,000,000 days of free hospital treatment were given and almost 900,000 persons patronized charity dispensaries, some change was needed which would make medical care available as a right and not a charity. Ninety-one per cent. of all deaths of persons of working age in 1916 were from diseases whose connection with important Pennsylvania industries had been established. It was claimed that one-half of existing sickness could be eliminated were preventive measures established. A large number of communities in the State had no active health work, and from 70 to 75 per cent. of the school children in the State were said to be physically defective. Responsibility for illness rested upon the community, industry, and the individual, and these three groups were meeting the loss from sickness in wholly unequal shares; the burden on the individual was often disastrous and out of proportion to his individual responsibility. Whether the corrective distribution should be accomplished by an extension of existing voluntary insurance agencies, or by a system based on a modification of the English or other European plan, he was not prepared to say. Physicians as a profession must face a great change in the social structure of the country. Dr. McAlister believed there was no danger of health insurance legislation at the present time, but the situation was similar in his opinion to that of a few years ago, when the Workmen's Compensation was under discussion and which suddenly became a law. Had the medical profession taken its part in the development of this legislation many of its present defects, so far as it applied to the profession, might have been prevented. He wished that every county medical society would appoint a special committee composed of its best constructive brains to study this subject alone, and if a commission were continued by the present legislature, that these committees would be prepared to meet with the commission and help it to arrive at a conclusion, so that there might be avoided the bitter experience of the British medical profession.

Health Insurance.—ISADORE STERN, Esq., of the Philadelphia Bar said that in 1917 the Pennsylvania Health Insurance Commission had been established to investigate: (1) Sickness and accidents of employees and their families not compensated under the provisions of the Workmen's Compensation Act. (2) The adequacy of the present method of treatment and care of such sickness and injury. (3) The adequacy of the present methods of meeting the losses caused by such sickness or injury either by mutual or stock insurance companies or associations, by fraternal or other mutual benefit associations, by employers and employees jointly, by employees alone, or otherwise. (4) The influence of working conditions on the health of employed persons; and (5) Methods for the prevention of such sickness or with a view to recommending ways and means for the better protection of employees from sickness and accident and their effects, and the health of employed persons and their families in the Commonwealth.

The commission after a year's study asked for an extension of time to set forth its findings to the Legislature in 1921. Mr. Stern suggested that the Phila-

delphia County Medical Society appoint a committee to work with the Health Insurance Commission in making the report fair from the physicians' standpoint as well as from that of any other individual or group involved. Many questions arose in contemplating the subject of health insurance: Would the State be successful in its effort to compel the insured to go to designated physicians? How would the physicians be selected under a system of health insurance? What percentage of illness is genuine? Would the necessity of dental care be put on a par with vaccination? Could health insurance be inaugurated at a reasonable cost? The commission was in the dark on this question. The data in the hands of insurance organizations were based upon the results of medical examination, and the only persons insured are those able to pass the physical test required by the insurance company. Would the adoption of health insurance place all physicians on the payroll of the State at a standard subsidy? If physicians were to be standardized why not inventors, lawyers, painters, and singers? Should health insurance in its greatest estate not compel a regular periodical examination by a physician instead of supplying medical aid after the person is sick? If a system of health insurance could be devised which would satisfy both the employer and the employed, which would not humiliate the employee by compelling him to consult a physician not his choice, or take against his will a form of treatment at a State institution; and if such insurance could be inaugurated at a reasonable cost, would not stifle individuality among physicians, or be paternal in its aspects, then he would favor health insurance. Health insurance on any other basis, he claimed, would be contrary to common sense.

Dr. FREDERICK L. VAN SICKLE, president Pennsylvania State Medical Society, said that he gathered from the discussion that the subject of health insurance as it related to the physician and the public, and in its problems was far away from what was known of American practice. The profession was in the position of knowing nothing of the finished structure of health insurance. A problem must be attacked with a certain amount of knowledge before it could be discussed intelligently. He felt that the Commission on Health Insurance had been very wise in not presenting to the Legislature immature, improperly constructed plans to be accepted unwillingly by the people. The Workmen's Compensation Law had been framed without the consultation with the medical profession which physicians would have been glad to give. If the Health Insurance Commission continued in power and would open the door, he did not doubt that the great profession of medicine in Pennsylvania would welcome an opportunity to collect facts and material and co-ordinate their work to assist the commission. He had encountered some "John Callahans" in his own experience, and remembered very distinctly one John Callahan, whose sickness problem was brought about by an evil which was fortunately now about to be eliminated. He disclaimed that the medical profession believed that poverty was caused primarily by illness; as president of the Medical Society of the State of Pennsylvania he welcomed the discussion, feeling that it had awakened an interest among physicians as nothing else could possibly do, and would do much toward arousing the medical profession to take the place it should have in the affairs of the State in such problems as the present. He emphasized the claim that the medical profession should have the same right as the legal profession in determining the price which should be set upon its services. He thought that every county medical society should have its committee interested in a health insurance measure which would protect the interests of the doctor. Many times the medical profession has made mistakes because it had failed to cooperate upon legislative matters. If health insurance must come, it was highly important that physicians get together in the framing of a measure which should be equitable to the people and to the medical profession.

Dr. L. WEBSTER FOX moved a vote of thanks to the gentlemen who had spoken, and as chairman of the Committee on Legislation expressed his personal appreciation of the information given. He agreed with Dr. VanSickle that it was essential that the profession should be alert and that it co-operate in an earnest effort to obtain a measure equitable to all concerned. So long as the profession was represented by Dr. McAlister on the commission he felt that the interests of the medical profession would be protected. Thanks were due also to Dr. VanSickle, who was working for the protection of the medical profession.

State Medical Licensing Boards.

CALIFORNIA STATE BOARD OF EXAMINERS.

Sacramento, October 22-23, 1918.

(*Continued from page* 470.)

CHEMISTRY AND TOXICOLOGY

(Answer ten questions only.)

1. Define organic chemistry.
2. Given dried kelp prepare resublimed iodine.
3. Give formula of formaldehyde and one method of its preparation.
4. Name four coal tar products used in medicine.
5. In what ways through blood and urine chemistry may acidosis be determined?
6. Give formula for urea and one method for its quantitative estimation.
7. Describe in detail Marsh's test for arsenic.
8. Give clinical picture of poisoning by $HgCl_2$ and describe treatment.
9. What poisons may cause sudden death?
10. State the toxicological effect of carbolic acid and the antidotal measures to be employed.
11. What is indican? Discuss the significance of its appearance in the urine and give test.
12. Give the chemical and physiological treatment of phosphorus poisoning.

BACTERIOLOGY AND PATHOLOGY.

(Answer ten questions only.)

1. Describe bacillus influenzæ.
2. Give ten different varieties of pathogenic bacteria with their microscopical characteristics.
3. Discuss the production of (a) active and (b) passive immunity.
4. What is a vaccine? How is it made?
5. Describe method of examining secretion from a chancre for treponema pallidum.
6. Mention five bacteria which grow best on blood-streaked agar.
7. Discuss adenomata and indicate their usual sites.
8. Discuss emboli and state under what conditions they are apt to occur.
9. Discuss bronchiectasis.
10. Discuss the pathology in acromegaly.
11. Describe the blood picture in pernicious anemia.
12. In what different ways may arterio-sclerosis cause death?

ANSWERS.

CHEMISTRY AND TOXICOLOGY.

1. *Organic chemistry* is the chemistry of the compounds of carbon.

2. *Preparations of iodine from kelp:* "The liquid obtained by lixiviating kelp contains the iodine as sodium iodide and potassium iodide. A concentrated solution of the impure iodide is treated with sulphuric acid, then distilled with manganese dioxide; the separated iodine condenses in a series of glass receivers."—(Remington's *Pharmacy.*)

$$2NaI + 2H_2SO_4 + MnO_2 = I_2 + MnSO_4 + Na_2SO_4 + 2H_2O.$$

3. The *formula of formaldehyde* is H·CHO.

It may be *prepared* by the distillation of calcium formate: $Ca(H{\cdot}COO)_2 = CaCO_3 + H{\cdot}CHO$.

4. *Four coal tar products used in medicine:* Phenol, cresol, beta-naphthol, resorcinol.

5. *Acidosis may be determined by:* (1) The determination of the alkali reserve, and carbon dioxide capacity of the blood pressure; (2) estimation of the hydrogen in concentration of the blood; (3) estimation of the acetone bodies (acetone, oxybutyric acid and

diacetic acid) in the urine; (4) determination of the ammonia quotient of the urine.

6. The *formula for urea* is $CO(NH_2)_2$.

Quantitative Estimation—Folin's Method: "Put 3 c.c. of urine, 20 grams of magnesium chloride, and 2 c.c. of concentrated hydrochloric acid into an Erlenmeyer flask of 200 c.c. capacity fitted with a short backflow tube (200 mm. long and 10 mm. in diameter). Add a small piece of paraffin to prevent foaming. Boil briskly, and then continue boiling moderately for forty-five to sixty minutes. Now cautiously dilute the mixture with water and wash it into a liter flask. Add about 7 c.c. of a 20 per cent. solution of sodium hydroxide, and distill off into decinormal acid. Usually about 350 c.c. of water should be distilled off, which takes about sixty minutes. Then titrate the acid with decinormal alkali (sodium hydroxide). Deduct from the number of cubic centimeters of acid taken the number of cubic centimeters of the decinormal alkali needed to neutralize it. The difference gives the number of cubic centimeters of decinormal ammonia which passed into the acid. Each cubic centimeter of decinormal ammonia contained in the distillate corresponds to 3 mg., of 1 per cent. of urea. Corrections for the ammonia content of the magnesium chloride used, as well as for preformed ammonia in the urine, are made separately." —(Stewart's *Physiology.*)

7. *Marsh's test for arsenic:* "This test depends on the fact that arsenic hydride is formed when nascent hydrogen acts on a compound of arsenic:

$$H_3AsO_3 + 3H_2 = AsH_3 + 3H_2O.$$

"A small flask fitted with thistle funnel and a delivery tube, as for the production of hydrogen, is used; pure zinc and hydrochloric acid are introduced, and after a short time the hydrogen is ignited. It is advisable to cover the flask with a cloth before igniting the gas, as an explosion may happen unless the air has all been driven out. If the materials are pure the hydrogen flame gives no deposit upon a piece of cold porcelain brought into it, but commercial zinc usually contains arsenic. When the purity of the gas is proved, a little solution of arsenite may be poured down the thistle funnel, which will produce a more rapid evolution of gas, and the flame will become larger and perceptibly colored. A piece of cold porcelain depressed upon the flame will be covered with a deposit of metallic arsenic. The films of arsenic are metallic looking in the thicker places, brownish near the edges; they are easily volatilized by heat, and dissolve in solution of bleaching powder. A portion of the glass tube from which the gas is burned should be heated to redness; the gas decomposes and a deposit of arsenic appears on the tube, which may be identified in a similar way, or may be converted into crystals of oxide by cautious sublimation in an open tube."—(Fisher's *Elementary Chemistry.*)

8. *Symptoms of acute mercurial (corrosive sublimate) poisoning:* "The nauseous, metallic taste is experienced during the act of swallowing. Within a few moment this is followed by an intense, burning pain in the mouth, throat, and stomach, the mouth and tongue are whitened and shriveled. There are vomitings of a white material, containing shreds of mucous membrane and tinged with blood, and bloody stools. Salivation occurs if life be sufficiently prolonged. Death sometimes occurs early from collapse, accompanied by convulsions, or in the deep coma; but in most fatal cases life is prolonged for from three to six days." (Witthaus' *Essentials of Chemistry.*)

Treatment consists in the administration of a moderate quantity of white of egg, and the removal of the compound formed, by emesis.

9. *Poisons which may cause sudden death:* Hydrocyanic acid, potassium cyanide, phenol, oxalic acid.

10. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The *treatment* consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal. At one time alcohol was much used; just now the older remedies (such as sodium sulphate) are more relied on. Soluble sulphates form with carbolic acid the insoluble sulphocarbolates, which can be removed by lavage.

11. *Indican* is indoxyl potassium sulphate; it is found (in excess) in the urine in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished persistalsis of the small intestines, as an ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc.

Test for Indican:—The urine is mixed with one-fifth of its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride; a few drops of chloroform are added, and the mixture strongly shaken 1 to 2 minutes. With normal urine the chloroform remains colorless or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.—(From Witthaus' *Essentials of Chemistry.*)

12. There is no known chemical antidote to phosphorus; potassium permanganate is efficacious; old French oil of turpentine is said to be the physiological antidote; fixed oils or fats must not be administered. The unabsorbed portion should be removed promptly by an emetic (apomorphine hydrochloride).

BACTERIOLOGY AND PATHOLOGY.

1. The *Bacillus influenzæ* is a small bacillus, about 0.5 mikron long and 0.2 mikron wide; it has rounded ends, is non-motile, does not form spores, is Gram negative, stains with Loeffler's methylene blue but not readily with the usual anilin dyes, it is aërobic and is difficult to cultivate.

2. *Ten pathogenic bacteria.*—(1) *Typhoid fever* is caused by the *Bacillus typhosus* of Eberth. This organism is rod shaped, with rounded ends, is from 2 to 4 mikrons in length, and about three-fourths of a mikron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

(2) The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Löffler's alkaline-methylene blue.

(3) The cause of *syphilis* is the *Treponema pallidum.* It is a very slender spiral, about 4 to 20 mikrons in length, with very close and regular turns, the curves vary in number from three or four to twelve to twenty. At each pole is a fine flagellum. It can move forward and backward, and also rotate on its axis. It is not settled whether division is transverse or longitudinal. It has not yet been cultivated on artificial media.

(4) *Plague* is produced by the *Bacillus pestis.* This is non-motile, with rounded ends, is about 1½ mikrons in length and a little more than half a mikron in breadth; it stains readily with all the anilin dyes, but not by Gram's method; it has no spores, and is not encapsulated.

(5) *The bacillus of tetanus* is characterized by its peculiar spore, formed at one end of the bacillus and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube, and produces gases.

(6) *Bacillus anthracis* is a large rod-shaped micro-organism, with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads; it is non-motile and non-flagellated; it is aërobic. It stains

by all the alkaline anilin dyes, and also by Gram's method. It grows on practically all media, as a film on potato, in tree form in gelatin stab, it liquefies gelatin and also serum.

(7) The *meningococcus* is a small, non-motile, non-flagellate coccus; it does not form spores, does not liquefy gelatin, is aërobic, and pathogenic; it appears in diplococcus groups, and may be found within or outside the cells; it stains readily with the ordinary anilin dyes, but is Gram negative. It grows readily upon meat infusions, and especially so on media to which ascitic fluid or blood serum has been added.

(8) Tuberculosis is caused by the *Bacillus tuberculosis.* This is a small, slender rod, slightly curved, occurring singly or in chains; it is 3 or 4 mikrons long, and about 0.2 to 0.4 mikron broad. It is non-motile, does not form spores, is aërobic, and stains with difficulty.

(9) Pneumonia is caused by the *Diplococcus pneumoniæ* (of Fraenkel). This is a coccus, occurring in pairs, it has a capsule, is non-motile, stains readily with anilin dyes and by Gram's method; it is aërobic and facultative anaërobic.

(10) *Gonorrhea* is caused by the *gonococcus,* which is a diplococcus with an appearance like that of two coffee beans; it is aërobic, can be cultivated on human blood serum; will not grow on gelatin, agar, bouillon or potato; it stains with ordinary anilin dyes but not by Gram's method.

3. *Active immunity* is that form of acquired resistance to infection which is brought about by the activity of the cells of a person or animal as a result of having had the disease, or as a result of artificial inoculation with a modified or attenuated form of the causative microorganism.

Passive immunity is that form of acquired immunity which depends upon defensive factors not originating in the person or animal protected, but is passively acquired by the injection of serum from one that has acquired an active immunity to the disease in question. It is a sort of secondary immunity acquired by virtue of having received antibodies actively formed by another animal that has had to resist the infecting agent in order to produce them.—(From Kolmer's *Infection, Immunity,* etc.)

4. A *vaccine* is an emulsion of dead or attenuated bacteria.

To prepare a vaccine: "All media and apparatus should be sterilized. Having isolated the organism, it is inoculated upon one or more agar slants, and after a growth of from five to seven hours (with streptococci) the growth upon these inoculated slants is taken up with salt solution, thoroughly shaken up in the diluting solution and standardized. The most practical way is to gently rub off the growth on the agar in about 1 or 2 c.c. of salt solution with a platinum loop. Then pour the bacterial emulsion into a sterile test-tube and repeat the process with three to five agar slants, until we have from 6 to 10 c.c. of the emulsion in the sterile test-tube. By heating to melting point in the flame a piece of glass tubing and attaching it to the rim of the test-tube (also melted), we have a handle with which to draw out the test-tube when heated about 1 inch from the mouth in a blowpipe flame. Drawing this out, we let it cool, and then filing the constricted portion we break it off and seal it in the flame. By shaking up and down vigorously from five to fifteen minutes, the bacteria are distributed evenly in the salt solution. A piece of platinum wire, twisted into corkscrew shape and fused in the draw-out end of the containing test-tube, helps in breaking up the bacterial emulsion. The sealed test-tube is then placed in a water-bath at 60° C. and heated at this temperature for one hour. Again shake. The constricted sealed end is again filed off and a few drops shaken out in a watch glass for standardization, and at the same time a few drops are deposited on an agar slant as a test for sterility. (Incubation for twenty-four hours should not show growth.)" —(Stitt's *Practical Bacteriology.*)

5. "*Treponema pallidum* is most easily demonstrated in chancres and mucous patches. . . . Tissue-juice from the deeper portions of the lesions is the most favorable material for examination, because the organisms are commonly more abundant than upon ulcerated surfaces and are rarely accompanied by other microorganisms. After cleansing, the surface is gently scraped with a curet or rubbed briskly with a swab of cotton or gauze. In a few moments serum will exude. The rubbing should not be so vigorous as to bring the blood, because the corpuscles may hide the treponema. Very thin cover-glass smears are then made from the serum. . . . A drop of India ink of good grade is diluted with 1 to 5 drops of water. A loopful of this is mixed on a slide with a similar quantity of serum from the lesion. The mixture is then spread over the slide and allowed to dry. After drying it is examined with an oil-immersion lens. Microorganisms, including the *Treponema pallidum,* appear clear white on a brown or black background, much as they do with the dark ground condenser."—(Todd's *Clinical Diagnosis.*)

6. *Five bacteria which grow best on blood-streaked agar:* Influenza bacillus, Ducrey's bacillus (chancroid), Koch-Weeks bacillus (conjunctivitis), Bordet-Gengou's bacillus (whooping cough), and Müller's bacillus (trachoma).

7. "An *adenoma* is a tumor that in its structure resembles an epithelial gland. It is frequently very difficult to tell whether it is a true growth or only an enlargement of a normal gland. In the new growth the tissues, though arranged typically, do not carry on any useful function. The secretion may be imperfect or there may be no duct through which it can escape. Adenomata arise from epithelial glands, are circumscribed, encapsulated, and rounded, or nodular. Have been found in all glandular tissues. Microscopically they consist of a framework of connective tissue, the meshes of which are covered by one or two layers of epithelial cells that resemble in shape and size those of the normal glands. The important point that distinguishes these growths from malignant ones is the relation of the cells to the basement membrane. In the benign adenomata, the membrane is preserved and the cells show no tendency to invade the surrounding tissue. If the connective tissue and epithelium are in normal proportion the growth is called a *simple adenoma;* if the connective tissue predominates, a *fibro-adenoma* If the tumor has a pedicle, it is known as an adenomatous polyp. Through degenerations, particularly colloid or mucoid, an adenoma may become very large through cystic formation. It is then called an *adenocystoma.*"—(McConnell's *Pathology.*)

Usual sites of adenomata: Skin, mucous membranes, breast, ovary, uterus, suprarenals, rectum, thyroid.

8. An *embolus* is a plug in the circulation; the process is called embolism. *Causes:* Thrombi, detached pieces from the heart valves, microorganisms, oil, fat, parasites, pieces of new growths. *Results:* Obstruction to the circulation; infarction; inflammation of blood-vessel; dilatation of blood-vessel.

9. *Bronchiectasis* is dilatation of the bronchi. "This is due to increased pressure within the bronchi or to some weakness of the walls, or to both. The weakening of the walls is most frequently due to chronic bronchitis. If it is extreme, simply the force of the inspired air may suffice to cause dilatation, but the increased expiratory efforts of coughing may add materially. When a part of the lung is collapsed (atelectasis) the impediment to the entrance of air leads to dilatations of the bronchi above the collapsed area. This is especially noted in children. The weight of accumulating secretions in the tubes is rarely the cause of bronchiectasis. Finally, in fibrous pneumonia the traction of the connective tissue, attaching itself, on the one hand, to the outer wall of the bronchus, and, on the other hand, to the pleura, may bring about considerable dilatations. The enlargement of the bronchus may be localized, when it is termed *saccular bronchiectasis;* or more uniform, when the names *cylindrical* and *fusiform* are applied, according to the shape of the bronchus. The mucous membrane may be almost normal in appearance in small dilatations, but more commonly is thickened and irregular on the surface. There may even be actual polypoid outgrowths, and ulcerations may occur when the secretions are specially abundant and irritating. Microscopically the epithelium is found to approach the squamous type; while the wall of the bronchus is generally infiltrated and cirrhotic. The exudation is generally purulent and copious, and may be very fetid. Occasionally it is thick and cheesy."—(Stengel's *Pathology.*)

10. *Acromegaly.* "This rare disease is especially marked by an overgrowth of the terminal portions of the extremities, and of the bones of the face. But there may be a general involvement of the skeleton—gigantism. This excessive growth is in the diameter rather than in the length of the bones, and is accompanied by local exostoses. Equally important and common is a general hyperplasia of the connective tissue of the body. Various lesions of the thyroid have been described, but they are not constant. The thymus may be persistent; there may be fibrous-tissue formation in the walls of the vessels and in the sympathetic ganglia. The skin is often pigmented. (The hypophysis is frequently the seat of hyperplasia.)"—Delafield and Prudden's *Pathology.*)

11. In *progressive pernicious anemia:* The marked feature of the disease is pronounced oligocythemia. This progresses rapidly, and in ordinary cases the number of red corpuscles sinks to 1,000,000 or less per cu. mm.; at the same time, changes in size (microcytes and megalocytes) and in shape (poikilocytes) make their appearance and reach grades rarely attained in other diseases. Nucleated red corpuscles are always present in some number, and are usually abundant. The largest forms (megaloblasts) as a rule predominate, but in some cases the smaller forms are more abundant. Karyokinetic figures may be found in the nuclei. Polychromatophilia is generally present. The leucocytes may be decreased or normal in number; in the late stages leucocytosis is not uncommon, and it may become extreme. The larger mononuclear leucocytes are usually more abundant than in health, and myelocytes often occur in considerable numbers. In the terminal leucocytosis of pernicious anemia the lymphocytes often predominate.

12. *Ways in which arteriosclerosis may cause death:* By rupture of a cerebral blood-vessel; thrombosis of a coronary artery; acute dilatation of the heart; rupture of an aneurysm; uremia; senile gangrene; myocarditis.

(*To be concluded.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	S. W. Welch, Montgomery	Montgomery	July 8
Arizona*	A. H. Williams, 219 Goodrich Building, Phoenix	Phoenix	April 1
Arkansas	T. J. Stont, Brinkley	Little Rock	May 13
California	C. B. Pinkham, Sacramento	Los Angeles	
Colorado	David A. Strickler, Empire Building, Denver	Denver	April 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 8
Delaware		Wilmington	
Dist. of Col'bia	E. P. Copeland, Washington	Washington	April 8
Florida*	W. M. Rowlett, Tampa	Jacksonville	June 16
Georgia	C. T. Nolan, Marietta	Atlanta	June 5
Idaho*	Ray H. Fisher, Rigby	Pocatello	April 1
Illinois	F. C. Dodds, Springfield.	Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	
Iowa	G. H. Sumner, Des Moines	Iowa City	
Kansas	H. A. Dykes, Lebanon	Topeka	
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. W. Mahler, New Orleans	New Orleans	July 1
Maine	F. W. Searle, Portland	Augusta	July 1
Maryland	J. McP. Scott, Hagerstown	Baltimore	July 15
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston	May 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 10
Minnesota	T. McDavitt, St. Paul	Minneapolis	April 1
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	St. Louis	June 9

THE CANCER PROBLEM—A CHAPTER IN MEDICINE.*

By ISAAC LEVIN, M.D.

NEW YORK.

CLINICAL PROFESSOR OF CANCER RESEARCH, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; CHIEF OF THE DEPARTMENT OF CANCER RESEARCH, MONTEFIORE HOSPITAL AND HOME.

Is cancer on the increase in the civilized world? Is the disease inheritable, or is it communicable from a diseased to a healthy individual? Is there any way of protecting oneself against the onset of the disease? Is there any hope for ever discovering a specific remedy which will relieve mankind of this awful scourge? These are the questions that agitate the lay mind, and which find ready discussion in the lay press.

The placing of these questions presupposes the conception that cancer is in every instance an identical constitutional, or possibly an infectious disease, and that the care and prevention of it is a subject in Public Health and public education.

The present publication aims to show that cancer is a common name for a group of neoplastic diseases, and that cancer is a subject for clinical study, medical research, and medical education, rather than a subject in preventive medicine and hygiene.

The education of the laity can best be done, in the opinion of the writer, by each individual family physician in his own narrow circle.

Definition of the Term Cancer.—The term cancer as it is applied at present designates a disease, the chief manifestation of which is the change of a normal cell of an adult organism into a cancer cell. With few exceptions the cells of an adult animal or plant possess a very limited capacity for proliferation and are endowed instead with differentiated and highly specialized functions. A cancer cell, on the other hand, is a cell which has lost its specialization and regained its power for proliferation which normal cells possess only during the fetal life of the organism. Furthermore, the cancer cells obtain the power of destruction of the normal tissues which lie in the path of their development and proliferation. There are two phases in this transformation to be considered in order to obtain a true conception of the etiology of cancer, and many points of both of these phases have been cleared up by the aid of experimental cancer research on lower animals and plants.

*Read by invitation before the Bronx County Medical Society on Feb. 19, 1919.

It will be shown later that the first phase in the formation of cancer, namely the transformation of a normal cell into a cancer cell, may be due to different causes in the different types of cancer. Cancer will thus be shown to represent in reality a group of pathological processes, having in common their neoplastic nature.

The second phase consists in the continuous endless proliferation of the cancer cells. This phase of the problem cannot be cleared up entirely until a better conception is gained of the phenomenon of growth in a multicellular organism. Two highly differentiated cells—an ovum and a spermatozoon—unite. As a result of the fusion of these two cells one undifferentiated cell is formed, which then begins to proliferate with the utmost rapidity and forms a complete organism, then suddenly the proliferation ceases.

The power which incites the first germinal cell to proliferate and then inhibits its further proliferation is as mysterious in the development of an organism as it is in the formation of cancer. Still, as will be shown later, many points in this second phase were elucidated with the aid of experimental and clinical cancer research.

Etiology of Cancer.—The possible rôle of a parasite: Ever since the discovery of the parasitic etiology of the large class of contagious diseases, the question has been debated whether cancer is also a parasitic disease. This opinion seems to have become even more plausible with the advent of experimental cancer research. Malignant tumors occur in nearly every species of lower animals and plants. In the human an inoculation of cancer tissue severed from the primary tumor succeeds only in the same individual. No inoculation of human cancer tissue has ever succeeded in another individual or in an animal. In other words, human cancer is not a communicable disease in any meaning of the term. In certain species of lower animals, notably in white mice and rats, the growth of a malignant tumor may be induced artificially by an inoculation into a previously healthy animal of a piece of fresh tumor tissue.

The tumors which develop upon such an inoculation of a piece of tumor tissue into a parenchymatous organ (brain, liver, spleen, kidney, or testicle) show many characteristics of malignancy described in human cancer. The tumor cells infiltrate diffusely, destroy and replace the substance of the organ, metastatic tumors develop frequently, and the animals die in a few weeks after the inoculation. The basic difference between these malignant tumors and human cancer consists in the important fact that the former may be propagated into normal individuals of the same species of animals.

A spindle cell sarcoma of a fowl, described by Raus, also represents a malignant tumor analogous to human cancer. The tumor infiltrates and destroys the surrounding tissues and metastasizes in the internal organs. The inoculated animals emaciate and die within three weeks after the inoculation. This tumor can be propagated not only by inoculation with fresh living sarcoma tissue, but also by means of tumor filtrate passed through a Berkefeld filter. In the white mice and rats described previously, it required the placing of viable cancer cells into a normal animal in order that a new tumor might develop. In the chicken sarcoma, on the other hand, an injection of a tumor filtrate which cannot contain living cancer cells, but only either a chemical agent or an ultramicroscopic organism, is followed by the development of the identical sarcoma in the new host.

Dr. Erwin F. Smith has described a disease of plants called the "crown gall" which he considers identical with human cancer. Crown gall is a new growth caused by a proliferation of a group of cells within a tissue, the normal cells of which ordinarily do not proliferate. The tumor grows invasively and destroys normal tissue. The plants become stunted and die; this disease is caused by a parasite (*Bacterium tumefaciens*) and may be induced artificially by inoculating the plant with a pure agar culture of the microorganism. The fact thus shown that malignant tumors of the lower animals and plants are easily transmissible into normal individuals, even, in the case of a chicken sarcoma by a tumor filtrate and in the crown gall by inoculation of a pure culture of the microorganism, again suggests the possibility of the parasitic origin of cancer. Indeed, Smith expresses an opinion based on his studies of the "crown gall" that all types of human cancer are due to an identical microorganism yet to be discovered.

A closer analysis of the results of experimental study as well as the human material indicates that the only possible function a parasite could have in the mechanism of the development of a malignant tumor would be to change one or a group of normal tissue cells into cancer cells and endow them with the power of limitless proliferation. The further development of a malignant tumor is a purely cellular phenomenon. When a small group of cancer cells from a primary tumor in the rectum metastasizes in the brain, and there develops into a discrete secondary tumor, the newly developed cells not only obtain the form of a cell of the rectal mucosa but align themselves in accordance with the glandular structure of the latter organ. It is inconceivable that any parasite could produce such results.

Pathogenesis.—The mechanism of immunity in cancer: As stated above, the ultimate cause which transforms a normal organ cell into a cancer cell remains a mystery. But the mechanism of the formation of a malignant tumor does not end there and, as it will later be shown, it is quite probable that such newly formed small groups of cancer cells may be destroyed by the resisting powers of the organism of the animal before they develop into a discrete malignant tumor. The mechanism of this resistance has been elucidated to a great extent by experimental research on inoculable tumors of lower animals.

Indeed, the most important phenomenon observed in the study of experimental cancer consists in the so-called immunity or resistance of certain animals to the growth of the inoculated tumors. This resistance depends upon a number of various complex conditions, most of which present as yet no tangible explanation. The phenomenon is a resultant of two component parts: the power in the inoculated cancer cell of unlimited proliferation and the reaction of the organism of the host. When a spontaneous tumor is inoculated it grows successfully only in a small number of animals used; frequently in less than 10 per cent. In subsequent inoculations with material taken from the implanted cancer cell it increases its proliferating power—its virulence. The fact, on the other hand, that a certain number of animals always retain their resistance to the tumor growth shows the influence of the reactivity of the host.

The usual method of propagating the tumors of the white mice and rats consists in a subcutaneous inoculation of a small particle of tumor tissue. The writer employed for a number of his investigations a different technique which consisted in an inoculation of the piece of tumor tissue directly into the organs, *i.e.* brain, kidney, liver, spleen, and testicle. The aim was to imitate as nearly as possible the conditions obtaining in the human. A number of interesting phenomena were observed by this method, which would have escaped the old method of subcutaneous inoculation.

The tumors which develop upon an inoculation of a piece of tumor tissue into a parenchymatous organ, as stated above, show all the characteristics of malignancy described in human cancer. The tumor cells infiltrate diffusely and replace the substance of the organ, consequently symptoms of clinical malignancy must occur as soon as a sufficient amount of an organ substance has been destroyed by the tumor. Indeed, these animals do not live any longer than about ten weeks after the inoculation, frequently die with much smaller tumors than are obtained by a subcutaneous inoculation, and true metastases form with greater frequency.

But of the greatest importance from both the theoretical and practical standpoint, is the condition of local organ resistance which the writer has demonstrated by this research method. In the experiments with an andenocarcinoma of the white rat, the writer observed that while the tumor grows when inoculated subcutaneously or into any other organ in a large percentage of animals used, it does not grow when inoculated into a normal testicle; but when a testicle is treated before the inoculation either with an emulsion of Scharlach R in oil or an emulsion of ether in water, an inflammation takes place in the organ accompanied with a proliferation of the intertubular connective tissue, and then the inoculation of the same tumor into the organ becomes successful.

This failure of the growth of the tumor in the normal testicle is not due to a general condition of the organism, but to a local action of the testicle on the tumor cells. The percentage of animals which are generally resistant to a subcutaneous inoculation of this adenocarcinoma is very small, but all the animals used for the inoculation into the testicle could not have been resistant to the growth

of the tumor, nor was the failure due to the mechanical influence of the tunica interfering with the expansion of the organ by the growing tumor, since other types of tumors grow readily in the testicle. The mechanism of this local resistance can thus be due only to an inhibitory action upon the cells of this tumor by the cells of the tubules of the testicle. This investigation further shows that it is possible to render the same testicle artificially susceptible to the growth of the tumor.

In another investigation the writer again found a striking proof of the possibility that a certain organ may react differently toward the growth of an inoculated tumor than the rest of the organism. It was shown that when a tumor inoculated subcutaneously is removed surgically, and then a piece of the same tumor is introduced into the subcutaneous tissue of another region of the same animal, the second inoculation will fail if the operation has been complete; but if the tumor at the site of the operation has recurred, then the second inoculation also succeeds. The writer repeated these experiments with the difference that the second inoculation was done not subcutaneously but into an organ. The results obtained coincided with the results obtained by the other investigations. The experiments were then varied so that the second inoculation was not done in one organ, but in two (liver and spleen) simultaneously, and the results obtained were quite remarkable. When the operation was radical and the subcutaneous tumor did not recur, then the secondary inoculation was not successful in either organ: on the other hand, when the operated subcutaneous tumor recurred, then in a certain number of cases the secondary inoculation succeeded in both organs while in another series of experiments the secondary inoculation succeeded in one organ and failed in the other.

These experiments show another instance of a purely local organ resistance in an otherwise susceptible animal. The subcutaneous tumor, for instance, recurs, and a subsequent inoculation into the spleen is successful, but a simultaneous inoculation into the liver fails. It is interesting to note that the spleen is the organ in which the inoculation most frequently succeeded, and the spleen is also the organ which is most frequently found diseased in tumor animals. Again as in the experiments with the testicle, there is an experimental proof of the supposition supported by the clinic that a diseased organ may be more readily susceptible to the growth of cancer.

The phenomenon of general inhibitory activity or general immunity of the organism against the growth of cancer is undoubtedly of paramount importance from the theoretical standpoint, but for the practical application of our knowledge of the pathogenesis of the disease, the factor of the local organ immunity of a healthy organ and the possibility that this resistance may be destroyed in a diseased organ is of great significance.

In men who reach the cancer age, only about 10 per cent. die of cancer; it is possible that the balance, or fully 90 per cent., are immune against the development of the disease. The general active immunity, the nature of which we do not know as yet, is consequently of such general occurrence that it seems plausible to suppose that when the local irritation in a certain organ is great enough, then cancer may develop even in an organism which is generally immune against tumor growth. It is thus obvious that the study of the conditions of local organ susceptibility or immunity may be of great importance in combating the disease and the care of such "precancerous conditions" in the various organs may present the real methods of prevention of cancer.

Meaning of Malignancy. — The experimental studies reported above show how malignancy, *i.e.* the proliferating and destructive power of the cancer cells on one hand, and the resistance of the organism, both general and local, on the other, manifests itself in the inoculable tumors of the lower animals. The identical phenomena observed as a result of pathological study of human material indicate the probable mechanism of this resistance of the organism.

It may be well to preface the discussion of this phase of the problem with the recapitulation of the characteristics of malignancy. The text-books of pathology state that malignancy in tumors means: *invasive growth* with destruction of normal tissue, *recurrenee* after operative removal, formation of *metastases* and *cachexia*.

The first characteristic is self-explanatory and is a purely local manifestation of malignancy. It will later be shown that formation of metastases as well as post-operative recurrences are also manifestations of local malignancy only caused by the invasive growth of the secondary tumors. Cachexia, which is seemingly a general constitutional manifestation, is not a constant nor even a frequent occurrence in malignancy. It most frequently takes place in cancer of the gastrointestinal tract, and is undoubtedly a secondary manifestation due possibly to absorption of dead cancer material, or to a secondary infection through an ulcerated tumor. The majority of cancer patients die without the evidence of cachexia through the destruction of vital organs caused by the primary or metastatic tumor. The difference between these two types of tumors consists only in the fact that in the former an unknown cause transforms a group of normal cells into cancer cells, while in the latter the development of a metastatic tumor begins from a group of already developed cancer cells transported from the primary tumor.

Bone tissue, in view of its characteristic morphological differences from all other tissues, presents a favorable object for the minute study of the changes taking place in the soil under the influence of tumor growth, and thus is best able to indicate the mechanism of the resistance offered by the organism to the growth of cancer. The pathological study of skeletal metastases of carcinoma by the writer elucidates many points in the pathogenesis of cancer and corroborates the findings of his animal experimentation.

Statistical study has shown that skeletal metastases occur in 2.5 per cent. of the cases of carcinoma of the stomach, in 3.03 per cent, of the uterus, in 52.3 per cent. of the breast, and in 66 per cent. of the prostate. The difference between 3.03 per cent. of skeletal metastases in carcinoma of the uterus and 66 per cent. in that of the prostate is very striking and cannot be explained by mechanical dif-

ferences, caused by variations in the anatomical structure of the organs. The topographic relationship between the uterus and the skeleton on one hand, and the prostate and the skeleton on the other is practically identical; so is the vascularization of the two organs, and it is as easy for the cancer cells from the uterus as those from the prostate to find lodgment in the bone marrow. The only plausible explanation of this difference between the formation of metastatic tumors of the two organs seems to be that while both the cells of the uterine cancer and the carcinoma of the prostate find lodgment in the marrow, the latter cells find there a better soil for development than do the cells of the uterine cancer.

A very striking instance indicating the existence of a peculiar affinity between the cancer cells and bone tissue was recently presented by Schmorl. He found in a series of cases of carcinoma, metastases not only in the bones of the skeleton, but in bone tissue abnormally developed in the cartilage of the larynx and trachea, and in one case a metastasis developed in a bone plaque on the wall of the aorta. In the latter case no metastases were formed in any organ with the exception of the bones of the skeleton and the bone tissue in the wall of the aorta. It is inconceivable that cancer cells should have been able to reach the small bits of bone tissue of the aortic plaque more easily than the parenchymatous organs.

Thus the probabilities are strongly in favor of the conception that tumor emboli are transported everywhere with the same ease and find lodgment in any part or organ of the body; the further growth, on the other hand, of the small transported group of cancer cells depends upon a correct metabolic affinity between the cancer cells on the one hand, and the organ cells, the soil as it were, on the other.

The metastasis begins its development within the marrow and when the group of cancer cells is small, the surrounding bone marrow appears quite normal; as the tumor nodules increase in size the growth approaches and invades the compact osseous tissue, or the compact osseous partitions of the cancellated bone, and then there begin to appear the characteristic changes in the bone tissue. It is generally accepted that there are two classes of skeletal metastases of carcinoma: *osteoplastic*, in which extensive new bone formation takes place around the metastatic tumor, and *osteoporotic*, in which the changes in the normal tissue surrounding the metastasis consist in extensive destruction of the compact bone. These two distinct conditions can easily be differentiated on gross inspection of skeletal metastases. However, the microscopic examination of the cases studied by the writer has shown that both conditions are usually present side by side. The difference in the gross appearance is due to the fact that in one case osteosclerosis or new bone formation predominates, while in another osteoporosis or the destruction of the old bone is mostly in evidence.

In the specimens studied by the writer both carcinoma cells and the small connective tissue stroma cells were found in immediate apposition to the walls of the lacunæ of the bone. The carcinoma cells were so frequently the only cellular elements within the lacunæ, that there cannot be any doubt but that carcinoma cells act directly as osteoclasts, destroy normal bone tissue, and then grow by occupying the space so formed.

On the other hand, the writer observed frequently that the cancer cells were surrounded by connective tissue fibrils formed in abundance from the old bone. These fibrils gradually unite in thick bundles and subsequently form new bone tissue. The latter is clearly formed from the constituent parts of the old bone tissue. On the other hand, the writer did not observe any hyperemia, inflammation, or any other abnormality of the bone marrow at the beginning of the development of the metastases, neither did he find any necrosis of the bone in any of the specimens examined. It must then be concluded that some unknown chemical irritant emanating from the carcinoma cells acts on the old bone tissue and stimulates its proliferation, and this new bone formation again acts as a protection to the organism against the further growth of cancer. It is thus evident that the malignancy and the destructive power of the cancer cell, as well as the power of resistance of the organism, are both local processes.

Spontaneous Cure of Cancer.—As seen above, the mechanism of the formation of osteoplastic skeletal metastases indicates an attempt at cure by the organism. That this attempt may be at least partially successful is seen from the fact that a skeletal metastasis may develop several years after a radical amputation of the breast without a local recurrence. In this instance the lodgment of the group of cancer cells in the bone took place before or at the operation, then for several years the bone tissue succeeded in checking the further development of the cancer embolus until, for some unknown reason, the protective action of the bone tissue failed and the metastatic tumor developed.

A similar condition in which an attempt at cure by nature is manifested, is cited by M. B. Schmidt. He examined forty-one cases of carcinoma of the abdominal viscera, selected at random from his autopsy material, for possible metastases in the lungs. In fifteen cases he found, on microscopic examination, small nodules either surrounded by a stroma of connective tissue formed apparently by the endothelium of the blood-vessels, or else consisting of a free group of cancer cells which seemed to have been transported more recently.

The coats of the small pulmonary arteries in which the cancer nodules were usually formed showed no lesion. The tumor cells apparently did not break through the walls of the blood-vessel from a focus of local dissemination, but were transported from the primary tumor or from a distant metastasis. Schmidt arrived at the conclusion that in carcinoma of the abdominal organs, cancerous embolism of the small arteries of the lungs occurs with great frequency; only a small proportion of these emboli give rise to metastatic tumors, because most of them are encapsulated and rendered harmless.

The mechanism of this spontaneous curative action by the organism consists mainly in the formation of a connective tissue capsule which surrounds the group of cancer cells and thus interferes with their further proliferation and development. This protective and curative action of the organism, while

à priori possible is apparently very inefficient, since authentic cases of spontaneous cures of cancer in the human occur extremely rarely, if at all.

Results of the Surgical Treatment of Cancer.—A malignant tumor represents in the final analysis an abnormality, a disease of a group of cells of a certain organ. Carcinoma of the breast, for instance, is a disease of a group of the breast cells. All the secondary metastastic tumors also represent accumulations of groups of diseased breast cells. Cancer thus begins with a local change in a group of cells of one organ; it then remains during a great part of its development a local disease, and even the secondary metastatic tumors represent in their respective regions purely local processes, caused by the growth of a minute group of transported cancer cells surrounded by normal tissue.

In view of this, it seems reasonable to expect *à priori* that results may be obtained by correct methods of purely local therapy. Indeed, in recent years the progress in such local treatment has been considerable. The main method of local therapy consists in the surgical treatment of malignant tumor. A great deal of progress has been achieved during the last two decades in the surgery of cancer. The modern surgical treatment is based on the fact that cancer spreads through the regional lymph glands; the surgeon strives to remove all the normal tissue adjacent to the malignant tumor and into which the latter spreads most frequently. The rule of modern surgery is also to make the incisions in the normal tissue as far from the tumor as safety will permit, and furthermore to remove all the regional lymph-glands. By the aid of these methods, which represent a very recent advance in the surgical treatment of cancer, Halsted and Willy Meyer obtained nearly 40 per cent. of cures in carcinoma of the breast. Wertheimer reports that 50 per cent. of the operated cases of carcinoma of the uterus remain cured, Mayo states that 25 per cent. of the operated cases of carcinoma of the stomach are cured, and so on. But notwithstanding this wonderful showing of operative statistics, clinical experience shows that only a small minority of the cancer patients remain cured.

In order to obtain a true estimate of the actual percentage of all cancer patients cured by surgical treatment, the writer has undertaken a comparative analysis between vital statistics and surgical statics of cancer.

The accompanying table was constructed in the following manner. The report of the U. S. Census in 1900 was taken as the basis of the statistical analysis. The total number of deaths from cancer in the registration area of the U. S. in the year 1900 were 17,286 men and women.

The first vertical column of the table shows how the cases were distributed among the various organs. The second vertical column shows the percentage relation of the number of cases in which a certain organ is involved to the whole number of cases of cancer in a certain unit of time. In order to obtain a correct numerical estimation of the percentage of cases of cancer cured by a certain operation, the relation of the number of operated cases to the whole number of cancer patients must be calculated. The following vertical column shows the manner in which the figures were deducted. The third vertical column shows the percentage of cases of cancer in each organ which are considered to be operable when first examined by the surgeon. This very necessary statistical information is rarely given in the published operative statistics.

TABLE I

Organ.	Number of Cases Reported by U. S. Census 1900.	Number of Cases of Each Organ, per Cent.	Number of Cases Operable for Each Organ, per Cent.	Number of Cases Cured by Operation, High Estimate, per Cent.	Number of Cases Cured by Operation, Low Estimate, per Cent.	Per Cent Relation of the Cured Cases of Each Organ to the Whole Number of Cancer Cases, High Estimate.	Per Cent Relation of the Cured Cases of Each Organ to the Whole Number of Cancer Cases, Low Estimate.
Bladder	180	1.0	..	30 0	6.8	0.15	0.05
Breast	1334	7.8	.	38 8	16.0	1.50	0.60
Head, face and neck	791	4.5	.	83.8	30.7	1.80	0.75
Liver	1784	13.0	..	..	..	1.00	0.15
Mouth, tongue and throat	692	4.0	..	20 0	13.0	0.40	0.30
Rectum	574	3.3		50 0	9.0	0.80	0.15
Uterus	2291	13.2	50	50 0	10.0	3.30	0 66
Stomach	4220	24 3	35	25 0	3.0	2.10	0.30
Abdomen	1107	6.4	..	12 0	4 3	0.40	0.15
Not specified	4313	24.9	..	..	.	3.80	1 04
	..	..	..	..	..	15.25	4 15

Since the percentage in carcinoma of the uterus and stomach is given in the published reports, the writer considered that the allowance of 50 per cent. of operability in all other organs and 100 per cent. in head, face, and neck would give more than a fair estimate of the present operative results. Primary carcinoma of the liver is a very rare disease and as a rule carcinoma of the liver is always secondary to cancer of other organs, frequently carcinoma of the stomach. Again, in order to be statistically more than fair to surgery the writer calculated carcinoma of the liver on the basis of carcinoma of the stomach.

The fourth vertical column shows the percentage of cases cured by operation as reported by the best operators for the cancer of this particular organ. The writer considers this a high estimate, since comparatively only a small number of patients can be treated by these surgeons. The fifth vertical column shows the percentage of cases cured by operation as reported by surgeons not so skilled. The ninth horizontal column, carcinoma of the abdomen, was calculated on the supposition that all the cases were carcinoma of the intestines, since these cases give the best operative results. The sixth and seventh vertical columns show the percentage relation of the cured cases of each organ to the whole number of cancer cases. The figures were obtained by multiplying the figures in the fourth and fifth vertical columns by the fraction representing the percentage of cases of each organ.

The last two figures of the sixth and seventh vertical columns were calculated in the following manner; unspecified cases of cancer must have belonged to one or the other organ. All the other figures in each of the two columns were added and the sum represented the high and low estimate respectively of the percentage of ¾ of all the cancer cases. One-third of this sum gives the percentage of cases of cancer in which the organ was not specified in the vital statistics and which would have been cured by surgery. Those not specified represent 24.9 per cent., or roughly ¼ of all cancer

cases. The total sums under the sixth and seventh vertical column show the high and low estimate of the actual percentage relation of the cured cases of each organ to the whole number of cancer cases.

The analysis of the table shows that as a high estimate 15.25 per cent. and as a low estimate 4.15 per cent. of all cancer cases can be cured by surgical treatment. Even on the supposition of the unattainable ideal, that instead of 50 per cent. all the cancer patients should come to the surgeon in the operable state, and all the surgeons should possess the skill of Wertheim, Halsted, Meyer, or Mayo, not more than about 30 per cent. of all the cancer cases could be cured by surgery. At present rather less than 10 per cent. of all cases are cured by surgery. It is safe to assume that there can hardly be expected much further progress in surgical treatment of malignant tumors. The latter are usually situated in close proximity to the vital organs, the injury of which would endanger the life of the patient, consequently there is a limit set to the length to which a surgeon may go in removing the normal tissue adjacent to the tumor. As a result of these limitations there may remain small islands of cancer cells in or near the operating field, even after a radical operation on a favorable operable case. For the same reason, the knife may inadvertently cut into such an island of tumor tissue and throw freed cancer cells into the opened lymph and blood channels; the malignant tumor will then recur in the same region or in a distant organ.

The second reason for the failure of radical operation and the subsequent metastasis formation in some distant organ consists in the fact that even in the early operable stage of the disease there may be present minute tumor nodules in the distant organs which cannot be detected by any diagnostic means at our command, but which after the operation develop into large metastatic tumors.

The Value of Radium and Roentgen Therapy in Cancer.—Another local method of cancer therapy seeks to destroy the small islands of cancer tissue which the surgeon left either in the operative field or at a distance. This is the method of *radiotherapy* or treatment by the aid of *x*-rays or radium rays.

When a plant or animal body is exposed to the action of roentgen or radium rays, there probably takes place the same atomic disturbance in the cells of the body as in a piece of metal or other unorganized substance, and as a consequence the rays injure the protoplasm, or more frequently the nuclei of the cells. This biological action differs quantitatively in accordance with the amount and character of the rays absorbed by the cells and the specific susceptibility of the latter to the action of the rays. When slightly injured the cell may recover completely, whereas if the injury is severe the cell dies.

All the tissue of the organism may be killed by a sufficiently large quantity of rays, nevertheless the biological action of the roentgen rays must be considered selective, inasmuch as quantities of the rays sufficient to kill a certain kind of tissue may leave adjacent tissues intact or only slightly injured.

In order to obtain this selective action, the rays must be distributed as evenly as possible through the organism, so that only a comparatively small quantity of the rays will reach each individual cell. On the other hand, a sufficiently large fraction of the rays must reach as far as possible from the surface of the body. Such distribution is only possible with hard rays, of which the penetration is much greater than the absorption.

The cells of malignant tumors are more susceptible to the action of the rays than the normal tissue cells surrounding the tumor. If the rays employed are of a correct quality and in a sufficient quantity, it is possible to destroy all the cancer cells in a certain locality, and at the same time leave the normal tissue either intact or so slightly injured that they ultimately recover completely.

The action of the rays on a malignant growth consists primarily in the destruction of the tumor cells, and subsequently the formation of sclerotic connective tissue which compresses and destroys the remaining tumor cells. In order to get a better estimate of the results obtained by this method of treatment, the writer made a statistical analysis of cases treated by himself and others. Of the very extensive literature on this subject, only those reports were selected in which the whole number of cases treated in a certain clinic were given, and not only selected favorable cases.

TABLE II.

Surgeon.	Number of Patients Treated.	Organ.	Died.	Discontinued Treatment.	Became Worse.	Not Improved.	Improved.	Became Operable	Clinically Cured.	Operable Cases.

Total	1002		..	..	....	.	..	51	56	..

The report of Doederlein's clinic is given, though the whole number of treated cases is not indicated, in order to show that a man of his clinical experience undertook to treat 35 operable cases with radiotherapy alone, but his cases are not included in the total calculation of the figures.

The table shows a total of 1,002 cases, which were all declared to be inoperable before the treatment with the rays began. Of those 57 were clinically cured and 51 were improved so as to become operable. There are 58 cases reported that were treated by radium alone which were in an operable stage; of these 35 belong to Doederlein and were not included in the calculation. The 21 cases of Wertheim must be deducted from the total sum of treated cases, but not from the clinically cured cases, since Wertheim does not consider a single one of his cases as clinically cured. The two operable cases of Chevron and Duval must be deducted both from the total sum and the number of clinically cured cases. There now remains a total of 979 cases, of which 54 are reported clinically cured. Of the 57 cases which became operable at least 25 per cent. or 13 cases must also have been clinically

cured, which gives a total of 67 cases or 6.7 per cent. clinically cured. These figures are similar to those reported by the writer, which are shown in the lower line of the table.

A therapeutic method which is capable of producing a clinical cure of 6.7 per cent. in a total of 979 inoperable cases of malignant tumors, is by far superior in its efficiency, as well as the number treated, to any therapeutic measure which was ever offered for this class of cases. But these numerical results do not indicate the full value of this method of treatment.

The writer reported previously on a case of carcinoma of the sigmoid treated for six months with *x*-rays which indicates the real value of radiotherapy in the treatment of malignant tumors. A brief résumé of the case follows: An exploratory laparotomy was done on the patient which revealed a carcinoma of the sigmoid and a peritoneal dissemination with minute metastatic nodules. The case was declared to be inoperable, the tumor was not removed and *x*-ray therapy was instituted. The patient died six months later from intestinal obstruction. The following points of importance may be adduced from the analysis of the case. Notwithstanding the continuous very large doses of roentgen rays, there was no injury to the skin, serous or mucous membranes, lymphathic glands, or parenchymatous organs; at the same time the islands of tumor cells in the peritoneal nodules were either completely destroyed and replaced by dense fibrous connective tissue or surrounded by the connective tissue and inhibited greatly in their growth. In over six months not a single one of the innumerable minute nodules found at the operation developed into a large metastasis. The original sigmoid tumor did not increase in size during this time; it is thus self-evident that the rays exerted a specific deleterious effect on carcinoma cells in the same quantity which left the rest of the organism intact.

On the other hand, this selective action has its distinct limitations; by analogy with recent physical studies on selective absorption of *x*-rays by various metals, it seems feasible to assume a selective action of the rays on a tumor is due to a greater absorption of the rays by tumor tissue rather than normal tissue. As a result, less of the rays penetrate into the next layer of tumor tissue than would have been the case if normal tissue were interposed between this layer of tumor and the rays. This difference in the mass of tumor offers the only explanation of the fact that the deeper part of the sigmoid tumor which was hardly more than 5 cm. from the skin, was not influenced by the rays, while at the same time the tumor islands in the peritoneal nodules, some of which were situated at many times a greater distance from the skin, were either destroyed or deeply influenced by the rays.

Two conclusions of great practical importance may be drawn from the analysis of this case: First it seems plausible to suppose that if at the operation the primary tumor had been removed and the radiation applied only to the peritoneal nodules a recurrence might have been prevented or delayed for a long time. This fact clearly indicates the importance of *combined surgical treatment and radiotherapy* of malignant tumors. A large tumor should be removed surgically even when a radical operation cannot be performed, then the small islands of cancer tissue may be destroyed by raying even when situated at a great distance from the skin. Thus even a metastasis may be influenced by the rays in its incipiency. Indeed the study of the writer on the prognostic and therapeutic significance of skeletal metastases in carcinoma of the breast cited above, indicates that even metastases in the bones may be influenced by roentgen and radium rays, and the patient may remain clinically well for a number of years.

The clinical and experimental investigations of the writer indicate that the first effect of the rays on every malignant tumor consists in the inhibition of the proliferating power, in the sterilization, as it were, of the cancer cells. The degeneration and destruction of the cancer cells and the formation of the sclerotic connective tissue take place subsequently under the influence of the rays. Moreover, this cell degeneration and cell death may not be due directly to the action of the rays, but takes place in the natural course of the life cycle of the cancer cell. This cycle consists of *youth*, or period of development; *maturity*, or period of function; and *senility*, or period of degeneration, which gradually leads to death. In parenchymatous organs, like the liver and the kidney, the first period is usually completed during embryonic life or at very early age; the second period continues through the whole life of the organism, and the third period is attained at the old age of the organism or near its death.

The life of an individual cancer cell, on the other hand, is very short; it changes rapidly from an embryonic into an adult and then immediately into an aged, degenerated cell, and this process takes place continually irrespective of any extrinsic aid. But in a malignant tumor the majority of the cancer cells are quickly rejuvenated before they reach senility through the fact that each cancer cell changes into two young daughter cells. When the rays arrest this proliferation, then the cancer cells, without any further outside aid, mature and degenerate. It is interesting to note in this connection that the life of the epithelium of the skin or testicle is nearly as short as one of the malignant tumors, and the rays act on these organs as specifically as they do on malignant tumors.

It is thus evident that the morphological appearance of radiated tumor tissue is not an absolute criterion of the therapeutic effect produced by the action of the rays on the tumor. The biological or clinical evidence of the arrest of growth or diminution of the size of the tumor is of undoubted value. A complete destruction of the tumor cells, which takes place in many cases even in large tumor masses, presents undoubtedly the most perfect result of radiotherapy. On the other hand, negative morphological findings do not preclude the possibility that the tumor was influenced by the rays. Radiated and non-radiated carcinoma tissue may have the same microscopic appearance, and still the former tissue is sterilized and may have lost to a great extent its power of proliferation and consequently its clinical malignancy.

The practical conclusion to be derived from these clinical and experimental investigations is the following: It is advisable to radiate malignant tu-

mors not only after an operation, but in a certain class of cases also before an operation so as to sterilize and inhibit the proliferation of those cancer cells which may be left behind or transplanted elsewhere in the course of an operation. Such a procedure does not prolong appreciably the time preparatory to an operation and presents no danger to the patient.

The fear expressed by some clinicians that the raying may occasionally irritate and increase the rate of growth of the tumor is unfounded. There is no clear experimental evidence of such irritating action of the rays on young proliferating cells. The result is always inhibition. The clinical evidence of the existence of an irritating action of the rays is also very vague and not convincing. One must keep clearly in mind the fact that any malignant tumor may suddenly increase its rate of growth and consequent malignancy without any relation to the instituted mode of treatment. In a series of 20 cases of carcinoma of the rectum which is being prepared for publication *in extenso* by the writer the following observation was made: In the cases in which an attempt at a radical operation was made the condition recurred with greater rapidity and malignancy than in those cases in which there was no operation done and only radium and roentgen-ray treatment given, or in which an exploratory operation was followed by radiations. Similar observations are surely made by any surgeon with a large cancer material. In this series of cases the malignant recrudescence of the disease was not caused by the operative interference, but accidentally took place after the operation. The same holds true of the recrudescences which occasionally may take place after radium or roentgen-ray treatment. Thus pre- and post-operative radiation of cancer as a method of inhibiting the proliferating power and the consequent clinical malignancy of the tumor cells is of undoubted value.

The best evidence from all the experimental and clinical research to date tends to the conclusion that cancer is neither an infectious nor a systemic constitutional disease. It begins its development as a local condition, as an abnormality, a disease of a group of cells of a certain organ. All the secondary metastatic tumors also represent accumulations of groups of diseased organ cells.

It is difficult to conceive of a *specific remedy* for a disease of this nature. Such a therapeutic measure would have to affect deeply the abnormal organ cells and at the same time remain innocuous to the normal cells of the same organ as well as all the other normal cells of the organism. It will require years of further research in medicine and biology before a better knowledge will be obtained of the functions of the cell and of the nature, structure, and functions of the endocellular enzymes. Only then will it be possible to find an antibody with such a fine adjustment that it will neutralize the abnormal proliferating power of the cancer cell and at the same time be innocuous to the other cells of the organism. The present method of crushing cancer tissue, embryonic tissue, or normal organ tissue and injecting it into a patient or into an animal preparatory to obtaining serum, the methods of autolyzing cancer or normal tissue and injecting it into a patient represent extremely coarse and crude conceptions of the fine mechanism of endocellular functions. The same is true in regard to the various attempts at establishing a chemotherapeutic method for the treatment of malignant tumors.

Thus far, at all events, every attempt at obtaining a general specific therapeutic measure against cancer has failed, and the correct combination of surgery, *x*-ray, and radium therapy represents the only method of treatment of the disease.

Further improvement in the actual results obtained must be looked for in the correct diagnosis of the disease in its early stages. Here again reliance should not be placed on the possible discovery of a specific diagnostic method.

It must be clearly borne in mind by every practitioner in medicine that, just as surgery and radiotherapy, without being specific remedies, accomplish a great deal in cancer, so can an accurate diagnosis in the very early stages of cancer be made by the aid of the various diagnostic methods in vogue at present in surgery and medicine. By the aid of methods of illumination (laryngoscopy, gastroscopy, proctoscopy, and sigmoidoscopy, and cystoscopy), by the aid of chemical and radiographic analysis of the gastrointestinal tract, the microscope, exploratory laparotomy, etc., physicians skilled in these various methods will be able in the majority of cases to recognize the disease early enough for obtaining timely treatment.

119 West Seventy-first Street.

PHYSICAL EXERCISE IN LATER LIFE.

By ROBERT E. COUGHLIN, M.D.,

BROOKLYN, NEW YORK.

THE writer once said to a gentleman well beyond fifty: "Do you still keep up your exercise?" "I surely do, and, what is more, I am going to continue to keep on exercising. Would you believe it, every one of my friends who ate, drank, and worked for the almighty dollar are dead; every one of them." This was his answer without any hesitation.

Of a heart specialist the writer asked the question very recently: "What do you think of exercise in later life?" To this question he promptly replied: "Absolutely necessary. Every one should have some particular form of exercise."

Another internist was asked: "What do you think of the after fifty heart and its ability to perform work and stand strain?" His answer was to the effect that the heart was pretty well played out after fifty and should be conserved.

Probably in the last analysis we shall find that the after fifty heart is able to perform good work and stand strain providing its structure is normal, as are other organs in the body when the individual reaches his fiftieth year.

Sir Herman Weber, who has recently died in his ninety-fifth year, attributed his longevity in great part to physical exercise. Both his parents died in their sixtieth year, his father from apoplexy and his mother of inherited heart disease. There was a predisposition in his family to life-shortening affections. He asserted that the stronger pumping of the heart improved the circulation of the blood and lymph in the abdominal organs with the help

of the stronger contractions of the diaphragm and abdominal walls, thus leading to improved oxygenation and to increased metabolism, appetite, digestion, and assimilation; therefore daily walks should be taken, if possible in the open country, and in all weathers. The amount of walking required depended upon the individual constitution, the state of health, and on the habits and occupation; also on the meteorological conditions—heat or cold, dryness or humidity, strong or light wind, or stagnation of air. The walk should not be extended to actual fatigue, but ought to lead to exhilaration and agreeable warming of the whole body. The pace, too, must vary in different persons, from less than a mile to three and four miles an hour.

To continue with Sir Herman Weber's observations: The following is his enumeration of some of the benefits accruing from walking exercise steadily kept up: (1) Increased afflux of blood to the muscles. (2) Increased nutrition combined with improved metabolism and production of body heat. (3) Increased exchange of fluid between blood and tissue. (4) Facilitation of the removal of waste products. (5) Preservation of the elasticity of the thorax and lungs. (6) Abundant supply of oxygen for the blood and the metabolism. (7) Maintenance of a healthy condition of the organs of circulation, from the heart to the smallest arteries, capillaries, and lymphatics. (8) Massage of the bones, keeping up the healthy condition of the bone substance and the functions of the bone marrow, and through this the formation of a sufficiency of blood efficient for the fight with hostile bacteria entering the blood. (9) Increased resisting power of the body against disease. (10) Stimulation of the brain centers which initiate the action of the different sets of muscles. In his own words, "Although I know that it is not alone to the exercise of the muscular system that I owe the health and strength which I retain in my ninety-fifth year, but that the attention to hygiene in general, to the digestive functions, to mental work, and the tenor of the mind, as I have explained in my little book on prolongation of life, has had a great share in it, yet I am sure that the keeping up of the muscular system has played a prominent part, and so does still. Spending daily two or three hours in the open air, walking as a rule thirty and more frequently forty or fifty miles a week, enjoying the beauties of nature, have had an exhilarating effect on the mind, and kept the whole organism and its resisting power."

Eight years ago Henry Stewart, then sixty-five and residing in San Diego, Cal., came face to face with the realization that his joints were getting stiff. He consulted a physician, who told him to swing them more. So Mr. Stewart packed a knapsack, and, with an old billiard cue as a staff, started out to take a walk. Mr. Stewart has been walking ever since. He has traveled 60,000 miles in that time, tramped over four continents, and has not heard his joints creak for so long he has forgotten what it sounds like. "I got as far as Jerusalem by a circuitous route," says Mr. Stewart, "and I started home by the back way." (From a newspaper clipping.)

From Decatur, Ind., we have the following: "Not only does John Schurger, eighty years of age, bear the distinction of having made the first abstract in Adams County, and of being the oldest abstracter and lawyer actively engaged in this profession in this city, but he is also probably the greatest walker in the country. In the fifty-two years that he has lived west of this city a distance of a mile and a half from the court house, he has walked to and from work every day, and made the round trip twice to three times on Sundays. A rough estimate makes his average walk a year 1,251 miles, or, for the fifty-two years, 63,052 miles, or nearly three times around the globe. (From a clipping.)

On September 20 of last year Mr. W. F. Duffy, Customs House Revenue clerk, in his sixty-fifth year swam from Brooklyn Bridge to Coney Island, a distance of sixteen miles, without special effort, just to demonstrate that he is practically as young as he was twenty years ago. The swim was in rough tide water, which makes the performance all the more remarkable. Mr. Duffy walks three miles before breakfast every morning. He is not a teetotaler, but would not average a high ball once a week. Tobacco he does not use in any form.

George Wiley, the oldest active cyclist, celebrated his fortieth birthday astride a wheel during the week of the six day race recently held in Madison Square Garden. In six day races alone he has traveled more more than 15,000 miles. He figures that all-told he has traveled or covered 100,000 miles during his career.

Eight years ago, when David Anderson was eighty-eight years old, he won first prize in a hundred-yard dash at the annual games of Clan MacGregor in Yonkers. He was considered an athletic marvel for his age, doing the short dashes and hurdles in near record time.

Among the annual visitors at Pinehurst, N. C., is Dwight N. Clark, of Woodbridge, Conn., dean of the golfing fraternity in the United States. Clark took up golf at the age of seventy-two, and is now in his ninety-third year. The veteran player limits his playing nowadays to nine-hole rounds, but it was only a few years ago that he beat all records for steady play at Pinehurst by disposing of one hundred rounds of holes each in exactly 101 consecutive week days. Clark's best round in recent years was forty-seven for the first nine holes of the number one course, made two years ago. His best recorded eighteenth hole round since he took up golf was an eighty-nine on number one course, made in 1897, when he was seventy-one years old.

Examinations for the Army and Navy service have shown that there are men who are physically fit at sixty and at sixty-two years of age.

On March 28, 1916, Mr. G. W. S. came to the writer because he had been repeatedly refused for life insurance. His age was forty-six, and it was reported that his blood pressure was too high. His business was and is insurance broker. He took no exercise at all except light calesthenics in his bathroom in the morning. He was a good eater and enjoyed his food and life in general, but he could not get away from the fact that he had been refused insurance and that his blood pressure was too high. An examination showed that he was perfectly normal in every way except that his blood pressure reading was S. 160, D. 115. He was told to eat a little sparingly, especially in regard to meat, to take a good dose of castor oil once a week, and to take a good brisk walk of at least five miles

one day a week, and to walk every day a mile or two. On June 30 he reported at my office and the following blood pressure reading was recorded: S. 150, D. 85. Reported October 14, 1915, S. 145, D. 90. Treatment was continued. Applied for first-class life insurance and was accepted, no liens or ratings on policy. This insurance was issued by the company which had formerly refused him insurance. One year later, on October 13, 1917, his blood pressure reading was 150-85. Kidneys normal. Kindly note that the diastolic remained normal. Body weight, 157 pounds. Was letting up on the exercise because he said he could not take the time. On December 20, 1918, his S. was 160, D. 100; no albumin; no sugar. Had given up walks practically because he had been so busy in his business. Weight 151½. Was advised to start in with the walks again, which he consented to do. Returned on January 28, 1919; S. 160, D. 96; weight 146½. Kindly note that his diastolic is lower and has kept low at all times except when he discontinues all exercise.

M. Banuelos and S. V. Pertella conclude, as a result of extensive experimental work, that moderate exercise diminishes arterial pressure, which is more marked in those who are in poor condition; violent exercise, on the other hand, raises arterial pressure. The mechanism involved in this process is probably nervous, hormonal, and chemical.

At this point the writer wishes to ask your indulgence and at the same time ask your forgiveness for injecting his own personal experiences into this subject.

For years he has been a firm believer in the opinion that most men do not exercise sufficiently to keep up the oxygenation of their tissues. He has preached this doctrine but has had few followers. He has written papers on the "Use and Abuse of Athletics," "The Medical Aspect of Athletics," "The Fatalities in Athletics," etc., and the same have received much favorable criticism and some unfavorable criticism. He has, however, consistently lived up to his opinion along these lines. Physical exercise in the young is apt to be overdone, but this is not so as age creeps on one. When the writer attained his fiftieth year he began to take inventory of his constitution. Had his years of strenuous exercise done his constitution any harm? He is able to say at this writing that he does not believe it has. To illustrate: In October, 1918, he was suddenly attacked with influenzal pneumonia, which he had probably contracted from patients during the beginning of the epidemic. He had thought himself to be in perfect condition after three months' life in a tent at the seashore. In fact he had taken an early morning bath with the temperature of the air and the water at 50 degrees, only a few mornings before. He went through the influenza pneumonia without any complications except night sweats to disturb him. He remained in bed twenty-seven days, and out of practice for six weeks. He lost in weight something like 35 pounds, twenty of which he has regained. Two weeks after recovery he resumed his walks with some feeling of anxiety, but was surprised to find that he could walk five miles in one hour and twenty minutes without any sign of tire or fatigue. He has since had his kidney secretion examined and checked up by a reliable laboratory and the reports were that the secretion was normal in every particular. His blood pressure is normal. His radials are soft and compressible. His heart is normal. He has what is known as "pep." Three evenings ago he accomplished the following without rest and with no sign of tire or distress: Danced two fox trots, two one-steps, three waltzes with different partners; immediately afterwards did shadow boxing for ten minutes, winding up with a few steps of a jig in jig time. Of course he perspired freely as any individual would under the circumstances, but the breathing was good and there was no out-of-breath feeling. He has always been a total abstainer. As the result of his observations of himself he has noticed the following: That a five-mile walk at a good pace, winding up with a Turkish bath, will abort a cold, unless it has the grip infection associated with it. That exercise will increase blood pressure both during the time of exercising and subsequent to it for a while, but after a few hours the pressure will be lower than it was before exercise, a difference as a rule of five points. Sea-bathing after light exercise on the beach will raise the blood pressure, but after a few hours the pressure will be lower than it was before the bath. The writer has taken sea baths when the water was 38° and the air 36°. He has taken a sea bath on January 7 in the water at Coney Island. He has walked to the Island, a distance of eight miles, and taken a sea bath in the month of December. Five years ago he swam in the month of October, when the water was 55°, a distance of one-half mile, beating his opponent, a fine swimmer and a trained athlete, who was fifteen years his junior. In 1897 he biked 84 miles in one day over very bad Connecticut roads. Of all forms of exercise he likes walking in the open the best. There is something very exhilarating in a long, brisk walk out of doors. The mind seems to be at ease, and for temperamental disturbances, transitory in character, there is nothing like a good long walk. Next to walking he would place a swim in the surf. It is the best cure there is for the grouch.

As an enjoyable form of exercise nothing can beat dancing in the open air. It is indeed an enjoyable form of exercise for the one who participates as well as an entertainment for the onlooker. Of course dancing indoors is not as good, but the atmosphere in the average dancing hall is as pure and probably purer than the air we inhale in the average gymnasium. For the later life period dancing is to be recommended, especially in the afternoons before crowds gather. In selecting the dancing partner it is very necessary that she be a good dancer, the better the dancer the more pleasure. To one who dances much appearances do not count for a great deal, but there should be some attractiveness and she should not be heavy in weight, or too slim in stature, though some short, heavy people are very light on their feet. From the man viewpoint any dancer much over 140 is too heavy when one dances the whole evening from 15 to 45 dances. Any dancer will tell you that there are no sexual sensations during the time of the dances, although to the onlookers this is very apt to be the idea in their minds. The writer would make the assertion that any one who confesses to sexual feeling during the dance is either a very poor dancer or abnormal sexually.

Another form of indoor exercise is handball. This

is indeed a very good form of exercise, but if one misses many times, as he is apt to do if he is playing with a younger opponent, it is apt to nettle him and irritate his temperament. Routine setting-up exercises never appealed to the writer. They become too irksome and tedious in the extreme. Calesthenics on the beach before a swim in the surf are very good. Golf is a good game, the writer has been told, but if one misses many times and makes many poor plays it is apt to get on his nerves and thus the good effects of the game may be overbalanced.

Boxing is too strenuous for the later life period. As a man becomes older, his movements become slower and more deliberate. For this reason the speed of the young man outweighs other considerations. Boxing is only for the young and the young only. The chances are too many against the older opponent and he may receive a very serious injury in consequence. Duelling appears to be a better form of exercise, as many men can testify. Wrestling should be a good form of exercise in later life. Bag punching and routine gymnasium work grow wearisome. Lawn tennis may be played by very active men in later years, and a few men beyond 50 have excelled as players, but it is a very fast game and essentially a game for the young.

Ice skating for the young and old is a healthful form of exercise, especially when the skating is done out of doors. Skating in ice palaces is not to be encouraged. They are apt to be very cold, raw, and chilly, and the atmosphere is bad as a rule. H. Toeppen (*N. Y. Medical Journal*, Feb. 2, 1907) mentions a man in Holland who was 70 when he won a well-contested skating race.

Conclusions: 1. After 50 degenerative changes are the most likely sequences of an early active life, especially if, as occurs often, the individual becomes sedentary in his habits.

2. As a rule, men over 50 do not exercise sufficiently to oxygenate their tissues. The dressing gown, the slippers, the newspapers, the easy-chair, the warm fire, the good dinner, the red wine at this time make their appeal along with the pipe, cigarette, or cigar.

3. There does not appear to be any great limitation of sports in those beyond middle life, and for this reason active exercise should be advised, especially in those who have led the athletic life.

4. Men who have done remarkable feats in later years show that the heart is not played out after 50. Added to those we have already mentioned we may name Weston, O'Leary, Hughes, O'Rourke, Blaikie, Radcliffe, Lombroso, Gaskell, Mace, Hocking, and Muldoon.

5. One is apt to compare the human heart with the carburetor of any automobile. Without a good working heart the human cannot go through life properly. There is a very big difference, however, on reflection. If your carburetor does not work properly you may have it repaired or substitute a new one but all you can do with the human heart is to repair it and build it up. An individual heart for each individual, and no substitution must be thought of. A truly wonderful organ is the human heart. It may be subjected to all kinds of strain in health with the chances, even in later life, that repair will go on if it is given half a chance.

6. Walking in the open air with free breathing and good style is as useful a form of exercise as any we know.
